I wonder if u could help me, i have a tri-band beam erected and am considering using 450 ohm feeder due to the less amount of loss on the line (as opposed to RG58)

The radio i am using is an IC-756PROII, with inbuilt ATU, will i be able to connect the feeder direct to the beam and run it straight into the back of my 756 (using 259 connector) ??

Or will i requrie a balun at either the beam or radio end???

hope you can shed some light on this, have got a bit confused with it

thanks in advance

Stephen Catterall

Unless you are running over 200 meters of coax, just go with the rg-8 size coax of a good brand. There is not that much loss in the rg-8 coax below 30 mhz to make any differance , especially by putting in the baluns.

No you can not just connect the open line to the so239 connectors. The rig is looking for something around 50 ohms and you already have a 450 ohm line with the open line. Most beams are designed to be fed with 50 ohm line also.

4. using an HP 8405A to measure SWR ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-01 02:14:04 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <1ZmdnY0padRtpyreRVn-sQ@comcast.com>
Source record: 65815

This is the next chapter in the antenna measuring saga. Today's adventure is trying to measure SWR with an HP 8405A Vector Voltmeter.

The measuring setup is a standard signal generator feeding a tee. One branch feeds the A input of the 8405A and the other a 20 db directional configured in reverse, that is feeding the out port. The assumption is the reflected signal will be read correctly on the in port. The in port is then terminated or connected to an antenna.

An open termination reads 180 degrees and a 50 Ohm termination reads 0 degrees and 55 db down from the input. (I assume 20 of that is the coupler so I am subtracting 20 from that reading - is that a correct assumption.)

Using the method to read the SWR on an antenna produces values very close to those from several SWR meters used as controls. When the output is terminated in 25 Ohms (2 x 50 Ohm terminators on a tee) the reflected signal reads about 24.5 db. (The B channel won't calibrate to within 1/2 a db so readings are estimates) Subtracting the 20 db bias yields 4.5 db. Within the error of the instrument this is pretty close to an SWR of 2:1.

Is there an error in this logic? If the instrument is working well enough to perform this calculation then it should support more complicated measurements.

Thanks - Dan

Matched line loss for 450 ohm ladder-line is indeed less than the
matched line loss for coax. But using ladder-line to feed a tri-beam
will result in an SWR on the ladder-line of around 10:1 so you will
be losing power because of higher SWR. If your coax run is less than
100 ft., I would just upgrade to a better grade of coax than RG-58.

> The radio i am using is an IC-756PROII, with inbuilt ATU, will i be
> able to connect the feeder direct to the beam and run it straight into

To do what you want to do will require a choke-balun at the IC-756.
In addition, what you want to do will require you to feed the beam
with a multiple of half-wavelengths of ladder-line. That means you
will be required to change the length of the ladder-line when you
change bands in order to get an impedance that your IC-756 tuner can
match. To use such a system, you have to know exactly what you are
doing. I do use such a system myself.

If you don't want to change the length of your ladder-line when you
change bands, your best solution is probably to go with a good grade
of coax like RG-8, RG-213, or LMR-400.

As I see it, your instrument with accessories (directional coupler,
attenuator, etc) can be used to measure the complex reflection
coefficient (Gamma) at the measurement plane.

Reading the mail, it seems have already worked out how to do that, and
to calculate Z given gamma.

If you want to determine SWR, you don't need the argument of Gamma,
you just need its magnitude rho. SWR=(1+rho)/(1-rho) where
rho=|Gamma|. (You are of course throwing away part of the measurement
data, the part that is the real power of the VVM. You could measure
rho with a directional coupler, calibrated attenuator and xtal
detector or a bolometer power meter... but they won't give you the
phase data that the VVM does.)

The return loss of VSWR=2 is 9.5dB, not 4.5 as you suggest. You need
to review some of these simple relationships. You also seem not to be
properly including the directional coupler in the calibration loop,
why the tee as described, doesn't the 8405A have a tee probe?

Is using a VVM an overkill for determining SWR? Probably, especially
if the complexity results in errors.

It would have helped if you disclosed the feedline length, it has
bearing on selection of solutions.

On the one hand, one respondent has told you 200m of RG8 is ok (that
is about 6dB of loss at 28MHz), and another has told you that the VSWR
on 450 ohm line will make it unattractive... you can only make these
calls if the length of the feedline is known (and the 450 ohm line
need not operate at high VSWR).

Do you rotate this beam? Will you need a coax tail at the rotator, or
have you some scheme in mind for using open wire line at this point?

There is probably already a balun at the beam feedpoint... but you
will probably continue need to use coax right close to the beam (the
rotator issue).

I would never use RG 58... use a good RG 8 or RG 213 instead of the
ladder line for proper impedance to the antenna and rig.

Got to admitt I ment 200 feet instead of 200 meters. That is less than 2 db
for rg8. Even the rg8x is only about 3.5 db for 200 feet at 30 mhz. By the
time you factor in the loss due to the swr and probably a couple of baluns
and the trouble to run open wire up a tower and in the shack you do not gain
much over a good grade of rg8 with open line up to 200 feet or more.

Not unattractive, just less attractive than if
it was a matched line case. I feed my 20m rotatable
dipole with 300 ohm ladder-line and put up with the
SWR loss in order to gain 20m/17m/15m/12m/10m
operation.

Where are these equations? I have searched the ARRL handbook for Gamma and did not find it. This is also the first reference to rho.

I was planning on the Z equation next, yes I remember that one from earlier in the week.

I am at my holiday place, and don't have reference manuals here, so I
can't give you specific references. I am confident that the main
formulas you need will be in both the ARRL Handbook and the ARRL
Antenna Handbook (though some versions of the ARRL publications
contain an incorrect formula for Gamma / rho). They will be in any
text on transmission lines.

Because I don't have the Geek font available here, I write Gamma to
mean the uppercase Greek symbol gamma (G). Textbooks should use the
symbol.

"Gamma" (meaning the uppercase Greek Gamma symbol) is the complex
reflection coefficient and Gamma=(Zl-Zo)/(Zl+Zo) where Zl and Zo are
complex quantities. rho (lowercase Greek rho) is the magnitude of
Gamma, rho=|Gamma|. VSWR=(1+rho)/(1-rho). You can rearrange these
expressions to suit your needs. For example,
Zl=Zo*(1+Gamma)/(1-Gamma).

Be careful, there are different notations and meanings in different
texts.

You need a reference!

HI
You might consider the Hexbeam, It is a five band antenna and very
compact and light. Google for it and you will find all kinds of info.
Eskay.

Some texts, like ITT's "Reference Data for Radio Engineers"
simply define rho to be complex as does Ramo and Whinnery.

rho = Eref/Efor = -Iref/Ifor = (Z-Z0)/(Z+Z0) =
(Y0-Y)/(Y0+Y) = |rho| /_ 2*psi

where psi is the electrical angle to the nearest voltage
maximum looking back toward the generator from the load.

Walter C. Johnson uses 'k' for the reflection coefficient.

It would also be nice it you had a 6 - 10 dB pad between the generator
and the directional coupler (DC); located right at the DC. You want
the source match to be set right there and the A probe to sample right
there.

>
>An open termination reads 180 degrees and a 50 Ohm termination reads 0 degrees
>and 55 db down from the input. (I assume 20 of that is the coupler so I am
>subtracting 20 from that reading - is that a correct assumption.)

No and no. Although an open isn't as bad a reference as some folks
think (in coax anyway), a better reference is a short. Then you know
that the reflection is 100% < -180 deg. (Where "<" means "angle of")
An open has a bit of fringing capacitance and a tiny bit of radiation
so it strays (sorry) from 100% < 0 degrees.

The other thing you need to do is normalize all future readings to 0
dB. Because, as Owen notes, you're throwing away phase information in
your quest for SWR only data, then start thinking in terms of return
loss. Return loss is measured (or calculated) against a 0 dB
reference. So from the beginning, when you get a reading with a short
(or open) that ratio becomes your 0 dB reference.

Are you saying that it you step the input power to the "B" channel by
1 dB, it measures a 1/2 dB change, or that with the same signal
applied to A and B they only agree within 1/2 dB?

If it's the former, then stop here and fix the instrument. If it's
the latter, you don't care; you are measuring ratios.
>
>Is there an error in this logic? If the instrument is working well enough to
>perform this calculation then it should support more complicated measurements.

There are errors someplace. A 2:1 SWR is a return loss of 9.55 dB.

Rho is mentioned on page 5 of AN77-3. Unfortunately, as I have
written a long time ago in other threads, Hewlett-Packard's authors
(and divisions) could not agree among themselves on a standard
notation for complex reflection coefficient.

The same holds true for the rest of the literature. My personal (and
others') choice is to use upper case Gamma for the complex reflection
coefficient and lower case rho for the magnitude of Gamma.

If this was standard then there would be no confusion.

>the source match to be set right there and the A probe to sample right
>there.

The 8405A manual indicates the use of a power divider, and then a pair
of equal-value pads. One side goes to the probe T for the A
(reference) probe and thence to the termination, and the other goes to
the probe T for the B probe and thence to the device-under-test.

The manual is quite clear that the A and B probes need to be connected
to points which are isolated from one another. You really don't want
the oddities of the load connected to the B side to affect the
voltage/phase of the reference signal seen by the "A" probe - it'd
certainly wreck the measurement.

Using a power divider, and resistive pads for isolation is one way to
do this. Using a pad followed by a dual directional coupler (as in
the experiment page to which Owen posted a link - thanks!) is another.

between sheds (hence require omni-directional)."

The benefit of simple and directional 915 MHz antennas is so significant
that you might consider making one site a repeater and all other sites
directional, communicating through the repeater. A small antenna can
have much gain at 915 MHz. You could conveniently use full-duplex (2
frequencies) for simplicity..

Best regards, Richard Harrison, KB5WZI

23. Dipoles and the rig's RF ground...

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-01 20:47:43 UTC
From: billcalley <billcalley@yahoo.com>

I realize that dipoles are balanced antennas, but does the rig itself still need an RF ground too? (I know the radio always needs a DC ground, of course). How about if the dipole is being used as a non-loaded "all band" antenna (IE: RIG--TRANSMATCH--LADDER LINE--DIPOLE) -- would this affect the need for an RF ground on the rig for operation in the dipole's non-resonant bands? Or is no RF ground _at all_ required with a dipole; unlike when using random wires or verticals, and other such un-balanced antennas?

Thanks!

Bill

Actually, my manual does not show this. Although I have the full kit
of a resistive tee, two 50 ohm "N" sampling tees and appropriate
terminations, I don't believe Dan does.

>The manual is quite clear that the A and B probes need to be connected

I've read this someplace, but again my version of the manual (unless
I'm really missing something) doesn't say it. Nevertheless, the
directional coupler provides the isolation between probes.

>You really don't want
>the oddities of the load connected to the B side to affect the

Actually, you do want to measure (include) the effects of the load on
the source. Although you ideally want the source to be unchangable
with respect to changes in the load (good source match). That is the
point of my suggestion to pad the source at the input to the coupler.
(Just as does paragraph 2.3 of Owen's reference)

But if the load -does- pull the source you damn sure want to know it
and account for it. The desired ratio is that between the incident
signal and the reflected signal. Sampling somewhere off in isolated
space via a tee and additional padding does -not- yield the incident
signal.

>
> Using a pad followed by a dual directional coupler (as in
>the experiment page to which Owen posted a link - thanks!) is another.

My point exactly. With the dual coupler the forward coupled arm -is-
measuring the incident signal -regardless- of what effects load pull
have on the source output.

With ladder line it is best to use a balun between the antenna tuner and the transmission line. An RF ground on the rig is then not required (you won't have RF voltages on the rig's chassis).

The thing about an RF ground is that due to the length of the ground circuit, the rig is often not grounded anyway.

I've got to clarify this a bit if I can...

If you have the full set of parts per figure 11 in AN77-3 and you are using them as shown, then with equal loads on the two ends, the circuit is essentially a resistive Wheatstone bridge in balance with the null detected by the difference between probes A and B.

In this case, the "incident" signal -is- measured by the A probe and the effects to the source by a changing load are incorporated into the measurement.

In the case at hand, at least as I imagine it, there is no longer an nice tidy resistive Wheatstone bridge, but some cabling and a directional coupler in the mix. In this case, the generator is no longer the "source", the source is the signal at the input to the coupler. It is my belief (unless I change my mind later) that a sample derived from a resistive divider remote from the input to the directional coupler is not a true measure of the incident signal.

Dan, my reason for this question is that you do not seem to have a load independent sample of the forward wave (if you are referencing measurements to the A probe).

Ideally you would use a dual directional coupler, otherwise, you need to isolate the A sample from load impedance variations and reflections using a largish attenuator for example.

If you are working the ratios out entirely from the B probe, eg B probe measurements on s/c and unknown load, then the A measurement becomes unimportant. Note that while this approach can give you enough info to measure rho and calculate SWR, it will not permit phase measurements. This approach dumbs the instrument down to a single channel RF voltmeter.

> itself still need an RF ground too?

If your feedline is balanced, that is it has equal and opposite currents on the two conductors, then there's no current left over to flow to or from ground and no need for an RF ground connection. All the current from one conductor goes back on the other. Feedlines can be balanced even if they're coax and/or the antenna is unsymmetrical; they can be unbalanced even if the antenna and feedline are symmetrical.

If the feedline isn't balanced, the difference current (that is, the difference between the currents on the two feedline conductors) will find its way to ground however it can. This often creates undesirable effects. But if you can't avoid it, it's better to provide a low impedance path for the ground current if possible. And that can sometimes be difficult to do.

(I know the radio always needs a DC
> ground, of course).

No, it doesn't. It needs an AC safety ground if connected to the mains, and a lightning ground if that's a possible hazard. But DC isn't important.

How about if the dipole is being used as a
> non-loaded "all band" antenna (IE: RIG--TRANSMATCH--LADDER

> verticals, and other such un-balanced antennas?

The trick is to get the feedline balanced on all bands. That requires either a truly balanced tuner, or a combination of a good balun and impedances on all bands at the balun which the balun can handle.

The VVM appears to do a great job of reading 'open circuit' at 180 degrees and
50 Ohms at 0 degrees, however it does not appear to read shorts accurately.
Shorts read at about 150 degrees instead of -180. They also degrade the incoming
signal to the point where is has significant noise on the monitor output line.
Is there a technique for doing this?

Thanks - Dan

The BAMA copy mentions it in paragraph 3-14. Later text indicates
that attaching the two probes to a single point is an appropriate way
to set phase-zero.

>> Nevertheless, the
>>directional coupler provides the isolation between probes.

I see the issue, and I think I was conflating two different sorts of
measurement regimes.

The splitter/isolator/pad arrangement I was referring to appears on
page 3-3 of the 8405A manual available at BAMA. It's what's
appropriate for doing an in-line test of a transmission line or other
network, where you want to see the effect of the network itself and
can measure (via probe B) at the network's output.

Page 3-4 shows a somewhat similar hookup, which doesn't include the
resistive pads... I presume because the device-under-test (an
amplifier) is assumed to have high isolation as part of its design.

Neither of these hookups wouldn't work for measuring an antenna, since
you can't measure at the antenna's output. Instead, using a
directional coupler provides the necessary isolation, and (as you
point out) lets you determine the incident and reflected signals
accurately.

Hmmm. In the general case, I believe you're correct.

I suspect that the setup shown in the 8405A manual sets up a specific special case, though. The diagrams and text seem to be defining a case in which:

- there is a physical and electrical symmetry in the T arrangement - that is, the power splitter is symmetrical, and the pair of attenuator pads between the splitter and the (A probe tap) and (device under test) are matched. The manual makes a point of this issue.

- The pads being used are matched to the system's transmission line impedance, so that any reflected signal coming back from the DUT/coupler sees a proper termination by the source (the pad and signal generator, in this case) and is not re-reflected.

In this particular situation, I believe that the incident signals reaching the DUT (the input to the coupler, in this case) and the "A" probe, would be identical... would they not? The proper termination of the reflected wave will mean that it won't re-reflect off of the generator and alter the incident wave. The "A" probe signal (off on its side of the "T") and a signal read out via the incident-wave tap on the directional coupler ought to be the same, once the coupling coefficient is taken into account... no?

Source record: 65842

I do not have the 8405a adapter kit or power splitter. I made "probe to bnc" adapters with 3/4 inch copper plumbing stock. The threads on the back of the probe are standard thread so it is easy to make an adapter and simply screw the probes in. This allows the A and B inputs to be connected to the directional coupler with bnc.

The measuring setup is a signal generator feeding a tee. One side of the tee connects to the A channel input. The other side feeds the 'output side' of the coupler. The B port is connected to the coupled signal port. The load is connected to the coupler input. This should read the reflected signal.

The signal generator is adjusted to read 0 dbm on the A port for all readings. (This is not possible for the 'shorted' readings). I do not have a pad between the generator and the tee. However, the above setup appears to support consistent readings.

~~~~~~
~~~~~~

OK.

1. Running a wire from your rig to ground will not do what you think it will. Any wire is a significant portion of a wavelength at HF and may be many wavelengths at VHF and UHF. On ten meters, for example, eight feet is almost exactly 1/4 wavelegth. If you recall your basic transmission line theory, whatever condition is present at one end of a 1/4 wave line has just the opposite at the other end. If you really do have a good ground connection at the grounded end of the wire, the other is an open circuit. Not very effective for grounding, is it?

The effect becomes less as you lower the frequency, but never completely disappears. It is possible to tune out this effect with a suitable coil and capacitor combination, but it really isn't needed anyway. MFJ makes a "ground tuner" or whatever they call it, and I suppose it does work, but think about this: If getting a good RF ground actually improves your signal, you have a SERIOUS problem in your antenna. More on this in the next paragraph.

2. RF does no good flowing through the earth. None at all. Dirt is a poor conductor at any ham frequency and you should do your best to keep your RF out of it. I suspect the idea that "ground" helps your signal came from the very early days of radio when frequencies were very low and wavelenghts were very long... miles long in fact. At those frequencies there are two factors which might make use of ground desireable: The earth is much more conductive at very low frequencies, and miles of wire for an antenna is not easily done. Under those circumstances, working a long wire against ground might actually be a good idea. None of that applies to ham frequencies, of course. At ham frequencies, RF works best when it's up in the air, all of it. Not in the ground, not in your shack, up in the air.

Keep that in mind and you can't go wrong.

Any antenna which requires a connection to ground should be shown the
trash can immediately. Ground (earth) is a lousy conductor and does
nothing to help your signal. RF belongs up in the air, not down in the
dirt.

If you find that connecting a ground wire actually improves your
signal, you have a SERIOUS problem in your antenna.

Most modern shacks have to long distance between the rig and ground. It's not equal to an ungrounded rig but you might experience hf in your shack.

This is best solved by a short ground cable to a proper ground rod.

The next best thing is to buy or build an artificial ground. It's very simple and can be made to cover all ham bands easily and will always give you a perfect length of the earth cable... By cheating of course - but it works!

Cheers

Get a virtual earth! They are easy to build for all ham bands!

It's basically a phasing unit for the earth connection which can null the
voltage on the earth at the RF Rig!

Cheers

Owen,

Yes, you are right. The single coupler doesn't isolate the channels. Putting a 10 dbm attenuator between the tee and the coupler changes the 50 Ohm reading. I think a dual directional coupler is required. I will have to put this on hold until that problem is solved.

Thanks - Dan

Dan

Are you open to trying to assemble something to measure the reflection
coefficient rather than to put the project on hold?
The HP 41952A Transmission/Reflection Test Set uses only one directional
coupler. It uses a power splitter at the input with a pad to level the
outputs from the "Fwd" and "Rev" ports. I can scan some info from the HP
41952 and E-mail them to you if you have interest in building something.
I would think it would be fairly easy to build devices for HF if you
already have a decent directional coupler.

Jerry

~~~~~~

They're great if you like your antenna two feet above ground.

The way you "null out the voltage" is by making that wire resonant and
resonant wires love to radiate. Nobody would intentionally install an
antenna below knee level, but that's what you're doing.

Busted any pileups lately? :-)

No it isn't.

It's best solved by keeping the RF out of the shack in the first
place. Even if you could "ground" your RF, why would you want to run
your RF through dirt? Is dirt a good antenna?

> . . .

I don't agree entirely with some of the recent short postings. And making a wire resonant doesn't make it radiate any better or worse than a non-resonant one. But if you have an unbalanced feedline (and by this I don't mean a symmetrical feedline like ladder line, but one of any construction with imbalanced currents) and consequential current from your rig to ground, that conductive path to ground will radiate just like an antenna -- any current flowing on a conductor causes radiation, regardless of whether we consider it to be an "antenna", a "ground wire", or a "transmission line". And as Bill points out, the location of a ground wire isn't usually what you'd choose for an antenna. Other consequential effects are that an unbalanced feedline has a net (common mode) current and so it radiates, too. The feedline and ground wire are also part of the antenna when receiving, so they'll be good at receiving noise that's generated in the house or radiating from mains wiring. All in all, it's not an ideal situation, although quite a number of people manage to get away with it.

"What would your recommendation be?"

I would use a vertical collinear omni antenna for the repeater and vertically polarized Yagis for each of the "sheds". To avoid stimulation of argument, I`ll say no more. You mainly need a line-of-sight path at 915 MHz between all remote sites and the repeater.

Best regards, Richard Harrison, KB5WZI

Jerry,

Thanks, the antenna handbook has a design for a bi-directional coupler that looks like it will work. At this point I think the next step is to separate the input to the A port from the reflected signal. Putting a pad in the circuit to increase isolation affected the reflected reading. I am also sorting through those readings.

Dan

No, that's very similar to figure 11 in AN77-3 that I mentioned below. Without inserting the device under test per Fig 3-3, but removing the right hand 50 ohm load and connecting the device there, reflection measurements can be performed. That's a technique described in AN77-3. The configuration is that of a Wheatstone bridge as mentioned earlier.

But I still submit that when you separate the bridge, insert a DC and some cabling, you lose the symmetry and the signal measured by the A probe is not necessarily the same as the signal incident at the input to the DC. Close maybe, but not something I would rely on.

Remember, when doing the calibration there is a 100% reflection. This can have a huge perturbing effect on the incident signal at the coupler input if the source is not well matched. That's why I originally suggested a pad right at the coupler input, especially if there is some cabling between the generator (or power splitting tee) and the DC.

No. The B probe, in the single directional coupler arrangement, is
not measuring -incident-, but reflected signal.

In any event, Dan has stated that he doesn't have all of this stuff
and is stuck using the DC only. My suggestion holds, put a pad at the
DC input, measure the incident at the DC input and of course, the
reflected at the coupled port.

Use either an 80 meter dipole fed by open wire or one of the off center fed
dipoles, often called a Windom.

>Bingo. Didn't seem like an "Electrical feature" to me :-)

Yeah. I'm not sure just why there would be substantial interaction if the two points are connected to the same test point, since the rated impedance is pretty high even without 10:1 isolators.

>But I still submit that when you separate the bridge, insert a DC and
>some cabling, you lose the symmetry and the signal measured by the A

>to the DC. Close maybe, but not something I would rely on.

The signal on the other side of the T-and-attenuator setup wouldn't be the same as the signal at the input to the DC, certainly, since the signal at the input of the DC would be affected by the reflected signal. I don't disagree with you there.

What I suggest, though, is that the signal on the "A" probe (at the other side of the T from the DC), and a signal as seen at the output of the DC's "forward" coupler line, ought to be very closely correlated. They'd differ by the coupler's coupling factor, of course, and there's be a bit of phase shift from the coupler (dependent on the coupler line length and the frequency). However, the loading at the coupler output from the load (or the calibration short) ought not to affect the signal appearing at the 'forward' tap on the coupler.

>Remember, when doing the calibration there is a 100% reflection. This
>can have a huge perturbing effect on the incident signal at the
>coupler input if the source is not well matched.

Agreed, and I don't suggest that measuring the incident at the coupler input is a good idea.

> That's why I
>originally suggested a pad right at the coupler input, especially if
>there is some cabling between the generator (or power splitting tee)
>and the DC.

Agreed.

>No. The B probe, in the single directional coupler arrangement, is
>not measuring -incident-, but reflected signal.

True. I was assuming a double directional coupler, and asserting that the "forward" output on the coupler will produce a signal equivalent

(except for scaling and perhaps a tad of phase shift) to a signal
taken from the far side of the splitter-and-pads "T".

>In any event, Dan has stated that he doesn't have all of this stuff
>and is stuck using the DC only. My suggestion holds, put a pad at the
>DC input, measure the incident at the DC input and of course, the
>reflected at the coupled port.

Yes, that should work quite well, and I think it'd give results pretty
much equivalent to [1] a dual directional coupler or [2] the
splitter-and-two-pads isolation arrangement.

Wes,

I only have copies of a few pages from the app note showing a bi-directional coupler. Is your reference that the note shows a bridge?

Thanks - Dan

I would use a fan dipole because of the harmonic relationship between
the frequencies you wish to operate on. Others might use a
trap dipole but traps always have some loss involved and may fail due to
moisture.

You are correct of course. I should have said a resonant antenna (or
ground wire) is easier to couple energy into, and in that sense, it
radiates better.

I use the W9INN trap dipole and I love it. The "traps" are not the
conventional coil/capacitor kind. Rather, they are a self-resonant
inductor with no separate capacitor, and they are rated at full legal
power as a result.

I run the antenna at 1500 watts on RTTY, probably the toughest working
conditions possible. It's been up five years through more than 40,000
contest QSOs and not a minute's problem.

W9INN is now an SK and I don't know if they are still in production,
but they are simple enough to homebrew if you have a grid dip meter.
The ARRL antenna book has more info on building this type of antenna.

>Forget about balun's and other widgetry!

And replace it with snake oil? Why?

>Get a virtual earth! They are easy to build for all ham bands!

He's probably fairly young , has his health, etc. The last
thing he needs is a "virtual earth" on the 2nd floor.

>It's basically a phasing unit for the earth connection which can null the
>voltage on the earth at the RF Rig!

It's basically a bandaid device to cure problems from using
poorly designed antenna systems. .

>If you don't want to build one, MFJ sells one!

I don't doubt that. They sell about everything else...

Seriously, if someone is on a 2nd floor, or even a ground
floor, there is no need for rf grounding in the shack at all.
All he needs to do is run complete antennas and there
is *no* need for any rf grounding. Sure, he needs safety
grounding for some gear, but that is taken care of by a
grounded electrical cord. RF grounding should always
be under an antenna that requires it. Not at a shack,
unless the antenna is fed from the shack. And that is
a bad way to live in general. All he needs to do is run
any complete antenna, such as a coax fed dipole, or
ladder line fed dipole, or a vertical that has it's own rf
ground under it. Adding a shack ground to any of these
scenarios is a waste of time. It also usually causes
more problems, than it hopes to cure...
If he's feeding any of those antennas with coax, which
I recommend for ease of use in any location, a balun
is his best friend, not widgetry.
I'm on the ground floor, and I use no RF ground
in the shack. Have no need for one. Grounding has
enough "wives tales" , etc, attached to it, to add
more snake oil, or bandaid solutions.
Lightning grounding is a whole nother story, but it also
belongs outside, and not in the shack so doesn't really
apply to his case of being on a 2nd floor and worrying
about a rf ground.

>until that problem is solved.
>

Dan, it seems to me that you should be able to make measurements with
a single directional coupler (DC)

You could connect your signal generator to the directional coupler via
a 40dB attenuator, and put the chan A probe T on the sig gen end of
the attenuator. This sample should be fairly independent of the
reflection from the unknown load (to the extent of the 40dB
attenuator), and so approximately proportional to the incident wave
alone.

The sample from the DC "reflected" port (properly terminated) is
fairly independent of the incident wave (depending on the F/B ratio of
the coupler) and so is approximately proportional to the reflected
wave alone.

Calibration of the B channel magnitude with a s/c and o/c taken as
rho=1 provides the basis for measurement of Gamma. The angle of Gamma
should be calibrated to 180 and o deg respectively.

BTW, the angle of Gamma for a 50 ohm termination is unimportant if rho
is very small. The angle of Gamma is real important for s/c and o/c
and ought be almost exactly 180 deg difference (if not, you have a
instrument problem).

Following this procedure, if the magnitude of the B channel on the
unknown load measures for example 9.5dB below the B chan magnitude on
a s/c, then the return loss is 9.5dB and the VSWR is 2:1. rho (the
magnitude of Gamma) is 0.333 and you could measure the phase offset
from the o/c angle to determine the angle of Gamma.

Why won't this work?

Owen

From: David <webreply@orbitcoms.com>
Message-ID: <TK5uf.166714$V7.16683@news-server.bigpond.net.au>
Source record: 65866

Hi,

I am wanting to check the match efficiency or return loss
of a C-Tap matching network that matches 50 Ohms in to 4500 Ohm load
with 2.5pF in parallel. Match at single Freqency = 45 MHz.

Using a 134nH inductor with Q of approx. 85
My calculations result in Cap to ground = 864pF, Cap to inductor = 102pF

I tried the match on the front end of my IF circuit and it appears to
tune smoothly and peak ok at 45MHz.

I then wanted to measure the return loss to see how good the match is.
Using the MJF-269, I get a lousey reading of 0.9dB. (almost everything
reflected).

Either my calculations are way off base, or I am not using the MJF-269
correctly. I also get lousey SWR (16.5), match efficiency below 5%.

I purchased the analyzer ages ago and have only used it to measure Vp of
coax till now.

Any help appreciated.

Thanks

I checked your numbers and they seem correct except that you
appear to have ignored the shunting effect of the tuned circuit's
resonant impedance. For an inductor Q of 85 I work this out at
around 3K (so then you have 3K || 4.5K). Further, was the Q
specified at 45MHz? If not it can only be a guide as to the
relative merits of the inductor since it is very frequency
dependent.

My advice is to use the 469 to measure what you have and then
work out what the inductor is really doing from there. If you have
a couple of suitable variable capacitors, put them in place of the
fixed ones and trim for the correct resonance/match, measure them
and then re-do the numbers.

Cheers - Joe (G3LLV)

Go for height first, then for length. Just build the biggest, highest damn dipole you can and feed it in the center with open wire line, 450 ohm line or 300 ohm TV lead, whatever you can get. Tune it at the rig with a balanced tuner. If need be fiddle with the feedline length until you can get it to work on all the bands you wish to use it on.

I've never had this approach fail me. Of course if you want to work a lot of DX on 80M, this is probably NOT the way to go (unless you can get it up 100 feet or more--at 300 feet it will sing no matter what you do, but you need real trees for that kind of height).

If the antenna is TRULY balanced and the feedline dressed well away from it
at right angles you should have no common-mode currents on the feedline.
That's the ideal case and in that ideal case you need no RF ground at the
radio. The ideal case, however, rarely ever exists in practice.

And end-fed wires can be a whole different ball game. I had to use a 16
foot counterpoise once to "ground" a rig in a 2nd story location when I
end-fed a very long wire with it.

A good rule of thumb is to separate them by at least a half-wave at the
lowest frequency. In this case that means about a meter (39") apart.

I run my T90A handheld into a Larsen dual-band mag-mount on top of my stereo. It works well for me, but I wouldn't recommend running anything more powerful using the stereo cabinet for a ground. As it is, I'm getting faint thumps when I key up. But a refrigerator or other appliance with a large size or even a set of 19" radials on the floor would work pretty well as long as you had enough metal to put the mag-mount on.

Why use a balanced tuner when a less expensive, easier to operate,
unbalanced tuner, in conjunction with a simple choke-balun, will do
just as well?

Insert the 2-wire choke-balun between the unbalanced tuner and the
balanced transmission line.

Reg.

That makes a lot of sense, Bill. It takes talent to take a rather technical
concept and put it into an easy to understand explanation. This post is
going in my Ham archive. Thanks again.

How wide is the area that can fit an 80M dipole? You should consider a
large horizontal loop aka Loop Skywire. I also use my loop on 6 and 2
meters with HB balanced tuners.

Not when they are orthogonally polarized. They can be 0.000 wavelengths
apart. I.e., in the OP's case, the 2M elements can be _mounted_ on the
70cm's boom.

I have a 6-el, close-spaced 2m vertical mounted on the forward boom of
my CC A3S. (Not that I give a crap much about 2M vert. propagation...)

Because a balun particularly lossy at high SWR -- with a balanced tuner
followed by a balun you present the balun with the correct impedance, so
it's at its best.

68. Why ground the transmitter?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-02 17:09:08 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <dpbmnj$j0c$1@nwrdmz03.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 65729

Transmitters, like any other 50/60 Hz AC power operated equipment, should be grounded for safety reasons.

This is done automatically via the AC power cable regardless of what floor level the transmitter is located.

If a balanced feedline is used to the antenna then no other grounding is needed.

If the antenna is an endfed wire then, for good RF radiating efficiency, there should be a low impedance connection between the TUNER and ground. The transmitter can still be left to its own devices.

If the transmitter and tuner are in the same box then the low impedance ground connection and the AC power ground are in parallel with each other. This results in an even lower impedance RF ground connection.

On whatever floor the transmitter + tuner is located, to obtain a low impedance ground, connect everything in sight together via the shortest reasonably possible wires, including hot and cold metal water pipes, the domestic plumbing system, central heating system, not forgetting the incoming water and gas mains.

The more the merrier! But only 2 or 3 distributed wires can be very effective.

Running a copper strip down an outside wall to a set of shallow buried radial wires in your back yard will be useful provided the length of the copper strip is NOT 1/4-wavelength at your favourite operating frequency. A single ground rod is wasted time, money and labour.

But, in general, if you live several floors up in a block of flats, a centre-fed dipole of random length, fed via a 450-ohm ladder-line, plus a tuner plus ckoke-balun, will be the more convenient and RF power-efficient option.

Any objections from the experts and Guru's?

Reg, G4FGQ.

======================================
Tim!

I don't know what design services you offer but you are WRONG.

You must have been reading the wrong comical magazines.

A choke balun is amongst the most power-efficient devices.

It consists only of a pair of wires wound around a ferrite ring. It is
just a very short transmission line of the same length as the wire and
has the same very low loss.

It has a phase shift of the same length of line. Which is immaterial
insofar as the tuner is concerned. It merely changes the tuner L and
C settings.

I don't know where you get your balun information, but you really need to do more homework, apparently. BALUNs can become quite lossy, depending on the impedence characteristics of the antenna you are trying to match at a particular frequency.

There are hundreds of sites where you can find this information....

http://www.cebik.com/a10/ant48.html is just one, for example.

Do some homework.

Roy-

Is this correct? As described, the "dielectric" is mostly air with some
plastic used as a spacer. I would have expected something over 90%.

Back to the question of how to get the water out. If there is a large
quantity, you might be able to pour it out. Beyond that, is there a
common technique used to dry-out cable? (I suppose a shop-vac could be
connected to one end and run for a while, on a day with low humidity.)

Sorry. I thought you were asking for help. My mistake.

Odd that you should answer the question when you already know the
answer, though.

To answer you unasked question: No, I do not have any test results, so
you are correct that I am just repeating the absorbed wisdom of others.
I'll be sure to qualify any similar answers I give in the future.
Until I get an HF system up again I won't be doing any measurements, so
don't hold your breath.

To ask you the same question: would you please post _your_ test results?

Pontificating from first principals is what you do if you are engaged in
preliminary design or the unpaid answering of questions.

Sticking to your guns in such cases is tilting over to philosophy,
religion, incompetence or internet trolling.

But you are sure enough of yourself to use capital letters when telling
me I was mistaken, so you cannot possibly be incompetent or a spinner of
trolls.

So I am confident that you are working from real, measured data, not
just derived results based on calculations or reasoning from first
principals. At most you are once removed from some reliable individual
or group who has done the measurements. It is very ungenerous of you
not to share a properly detailed report on your experiments, or a
reference to the report of the folks who did do the work -- a link to a
page will do, or even a reference to a periodical or book should the
information not be available on the web.

I'm ready to change my thinking just as soon as I see something
credible, and quite interested in the results because I don't see the
point in building a balanced tuner if my existing unbalanced one will do.

Thanks.

My link coupled tuner (Johnson Matchbox) cost me less than 60 USD, I
can tuner faster than a T-type tuner, doesn't need nor use a balun.
(Read one less component and its associated loss). So why would I want
to replace it with something that works almost as good?

To dry out a cable which is partially air-spaced, get a cylinder of dry air or nitrogen and allow the gas to seep through it under a pressure of two or three times atmospheric. It may take several days or more for a length of 100 metres. Measure capacitance at intervals for stability.

It speeds things up if the cable can be warmed in an oven at about 60 degrees C. You don't want to melt the polyethylene.

The foregoing is based on a vague memory of an episode about 50 years back.

>Any objections?

If there is no need for an RF ground, I think trying to
conjur one up is silly and just adds more problems.
IE: "virtual grounding"...Thats sillyness... :/

IE: ..
>On whatever floor the transmitter + tuner is located, to obtain a low
impedance ground, connect everything in sight together via the
shortest reasonably possible wires, including hot and cold metal water
pipes, the domestic plumbing system, central heating system, not
>forgetting the incoming water and gas mains.

Sounds like a good way to connect to a bunch of noise to me...
After all, ground is a noise source.
If the antenna is not fed directly from the shack, IE: end fed wire
from a shack tuner, I don't try to "rf" ground the shack. Being I
never feed directly from the shack, I never try to ground it.
I could be on the ground floor, or the 22nd, and I would not notice
any difference in operation. Also when mobile...Sure , I make sure
the ground under the antenna is very good. It's the rf ground. But..
I rarely bother grounding my rig itself. There is no real need.
Besides, it is grounded, when you consider the (-) power connection.
I know I'm a weirdo, but I think there are few cases where a ground
is required in radio operation. Overall, ground is either a bandaid,
or a
noise source, or a good place to lose useful rf due to excess
ground losses. The latter due to poor rf grounds under an antenna.
I think the farther one can stay away from grounds the better, overall.

I've never had much use for ground, except under vertical antennas, or
to safety ground high voltage gear like tube radios and amps.

What would you recommend for a wire antenna if there was enough room
for
an 80 dipole? Assume use for 80M , 40M and 20M,
.....

Myself, I prefer separate dipoles for 80,40,20 fed in parallel with a
single
coax feed. I spread the antennas far apart to minimize coupling.
Why? Pretty much standard dipole performance on each band.
No tuner needed, and thus no tuner losses. Instant band switching.
About as efficient as anything you can run for the bands it's
designed for. Of course, you would need six tie off points, but
those can be trees, fences, whatever.. In the winter I usually
convert my 20m legs to 160m. In that case, it's a 160m "Z"
dipole, and the normal 80 and 40 dipoles fed in parallel. But, so
far this year, I've been lazy and it's still in the summer mode with
80-40-20. The 160 legs have an insulator at the "20m" point, and
I bypass those for 160 with a jumper. I can also set it up to run
on 80m as a turnstile as the 160 legs also have insulators at
the "80m" points. Well...There you have it... MPG will vary... :/

All kinds of peculiar things can happen with voltage baluns and current baluns which have a definite impedance ratio.

But my comments apply to a CHOKE balun, the most simple form of balun. It is a pair of wires wound together on a ferrite ring. It is just a very short 2-wire transmission line. For longitudinal currents it is an RF choke, the 2 wires being effectively connected in parallel.

The impedances between which it can work are indeterminate. There is no impedance ratio.

When connected between a balanced line and an unbalanced tuner, the tuner can be an ordinary simple L, Pi or T network.

If you happen to have a balanced tuner, lying around doing nothing, then by all means use it without a balun. But if you don't have a balanced tuner, as is very likely, there's no need to make one. Just use a common or garden unbalanced tuner, which nearly everybody has already got, with a CHOKE balun.

The hardest part of making a choke balun is obtaining the ferrite ring. 50mm outside diameter, 30mm inside diameter, permeability 200-400, about 16 turns of twin, flexible, stranded, speaker cable, will be OK for the HF bands. Or similar.

All the very best for 2006.

Reg, G4FGQ.

Use a TV-set flyback transformer core; see:
"another balun design", by Fred Brown, W6HPH, in Ham Radio magazine
of May, 1982, pp. 54-57

"Three Baluns for a Buck" by Donald E. Lively, W6SJQ, from a magazine
which didn't print either its name or the date on the pages I saved!
but it basically says the same thing as the HR article.

A hint on p. 37 of the August, 1987, QST describes "The Baby-Bottle Balun",
an air-core balun based on DeMaw's article "Simple Coreless Baluns" (QST,
Oct. 1980, p. 47; which I apparently didn't appreciate enough to keep).

Owen,

That idea seems to work. I set it up and then looked and the 'interference', the change in phase based on changing the pad. Zero pad showed several degrees phase shift from -40 dbm, 10 dbm showed small shift, and 20, 30, and 40 were all about equal. I decided on 20 dbm as a practical base.

Thanks - Dan

This doesn't make sense... are you using "dbm" to mean decibels of
attenuation, usually written "dB".

The units "dBm" are usually written to qualify a power level with
respect to one milliwatt.

The attenuator on your sig gen might be marked in dBm, but that
applies to the combination of the oscillator, possibly its level
meter, and the attenuator as a system.

Using the wrong terms for things is often a result of a concept gap!

A 20dB attenuator will reduce the effect of the reflected component to
about the same level as you would expect from a practical directional
coupler, more attenuation is better if you have the power from the sig
gen and the VVM probe chan can operate at the higher input level.

There's a figure at the bottom of
<http://www.tpub.com/neets/book10/42.htm> that shows current distribution on an antenna. Is there some book or source that describes how figures B and C and produced?

I'm guessing that one starts with an open ended transmission line, and looks at how the E and B fields are distributed along it. Then one peels the open end back until the two lines are pointing away from one another. One then ends up with E fields pretty much in a plane directed from one point on one side of the wire to the similar point on the other wire. Similarly the B fields encircle each wire. On one side they have a CC direction and the other a CC direction (looking in the direction of the current).

As a separate item, it would also seem that for a transmission line that is open ended the current flowing in one wire induces a current to flow in the opposite direction in the other wire. That is the current flows in the one wire because it does so by induction rather than it being physically part of the other wire.

>. . .

That only prevents one of the two ways common mode current can be created, by coupling. It can also be created by conduction. A common example is a coax-fed dipole, where the current in the outer feedline conductor splits between the antenna conductor and the outside of the coax. An equivalent problem can occur when a dipole is fed with symmetrical line such as ladder line, and one conductor of the line is connected to the rig's chassis at the rig end. The current on the inside of the chassis is equal to the current from the "hot" conductor, and this splits between the transmission line conductor and the outside of the chassis. A detailed explanation of conducted common mode current can be found at http://eznec.com/Amateur/Articles/Baluns.pdf.

I suggest that you start with an unloaded monopole or some very simple antenna with a well known impedance. (You will of course have to know and allow for the effect of the finite ground plane.)

You also need to take measures to prevent coupling between the antenna and the outside of the feedline. The ground plane you mention will help, but there can still be substantial coupling. Some high impedance ferrite beads at the feedpoint and another set about a quarter wavelength down should reduce the coupling to a small value.

Reg,

I am planning on building an antenna based on midload.exe. For some reason the 'notes' do not appear so I cannot read them.

I plan to feed the antenna with coax. What are the hookup instructions? Is the coil actually cut? What does link coupling refer to?

There is a similar antenna in the ARRL handbook, however it does not appear to be cut. The shield is connected to a center tap and the coax center is tapped a few turns out.

The program predicts 40 turns with a coil tap of .8 turns. Which connection is this?

Thanks - Dan

Source record: 65754

I proceeded before reading this note. The procedure was to zero the phase meter on an short and then to test the loaded 2m vertical. The result was +10 dbm forward (before the 20 dbm pad) and -50 dbm reflected. The coupler measures about -14 dbm. The total was about -60 dbm, with 34 db of that due to the pad and coupler. The net is -26 db forward - reflected.

(The phase angle and reflected ware very touchy. It was almost impossible to adjust by changing frequency. It was easier to 'adjust' it by sitting very still and moving my arm.)

The antenna is a copy from the ARRL handbook. It is a 4 inch segment, a 1 inch long by 3/4 inch diameter 5 turn coil, and a 4 inch tip. It is mounted over a 2 foot square aluminum plate. This antenna should have an input impedance less then 20 Ohms.

How can it measure very close to 50 Ohms? Is there something wrong with this analysis?

Thanks - Dan

How did you arrive at this figure? I wouldn't hazard a guess without
modeling it.

> How can it measure very close to 50 Ohms?

1. Inductor loss.
2. Effect of finite size ground plane.
3. Coupling to feedline.
4. Measurement error.

Is there something wrong with
> this analysis?

I don't know. What should the impedance really be?

A lot of authors of antenna and electromagnetics texts avoid the issue. There's a decent analysis in King, Mimno, and Wing, _Transmission Lines, Antennas, and Waveguides_. The problem is much more difficult when the antenna is longer than a half wavelength or when the wire diameter becomes significant. In those cases, a much more complex calculation is necessary, with only approximate results being available from closed form solutions. Numerical solution of a triple integral equation is the method usually used. That approach is necessary when there are nearby current-carrying conductors, since that alters the current distribution in ways which are usually too complex for other methods. A brief discussion of several methods of approaching the problem can be found in Sec. 14.11, "The Cylindrical Antenna Problem", in Jordan and Balmain, _Electromagnetic Waves and Radiating Systems".

Using a transmission line as an analogy for antenna operation works just well enough to be dangerous. While it's a way to get an intuitive understanding of antenna operation, taking it too far can lead to some erroneous conclusions. One fundamental limitation is that classical analysis of a transmission line depends on the assumption that no radiation occurs, and that's certainly not the case for an antenna.

Yes, that's correct. If you assume that the entire field from one wire couples to the other, which is strictly true for coax and approximately

true for twinlead, it follows from Ampere's law that the current on one wire must be equal and opposite that on the other. This assumption of field coupling isn't true for an antenna, although coupling does indeed exist and it does have a profound effect on the currents.

97. Still have problems reading MJF-269 Analyzer

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-03 02:45:50 UTC
From: David <webreply@orbitcoms.com>
Message-ID: <yzluf.167174$V7.159957@news-server.bigpond.net.au>
Source record: 65758

Hi,

I have a matching circuit that matches 50 Ohms to 4500 Ohms in parallel with 2.5pF at 45MHz.

The coil was measured at 147nH with a Q of 50 at 45 MHz.

The circuit is a C-Tap typology with following values.

Tap input to ground = 784pF
Tap to hot side of coil = 92pF
Par inductor = 147nH

My design calculations predict Loaded Q = 26 and BW = 1.7 MHz.

I used a 50p trimmer in par with 68pF cap for top of tap to fine tune.

A 4k7 resistor and 2p2 cap were placed across the output to simulate the correct load.

The test results show BW = 1.7 MHz and Loaded Q = 24.7 (agree with calculated values).

When installed on the IF front end, the expected sensitivity is achieved when tuned. This would indicate most of the signal must be getting through or sensitivity would be effected due to mismatch.

All seems to look ok but when I attach the MJF-269 Analyzer I get impedance of 280 angle 35 degrees (240 -j 179) for the impedance, I get SWR = 6.1 , return loss of 2.8dB and match efficiency of 48%.

I cannot understand why there is such a discrepency between the design values and tested results (using sig gen, spectrum analyzer and power meter) compared to the MJF-269.

Is there something I am doing wrong here or is it a mis-interpretation of displayed values ?

Thanks for any help.

Thanks very much for the comments. They were helpful.

I managed to find "Neets Module 10-Introduction to Wave Propagation, Transmission Lines, and Antennas", a Naval Electrical Engineering book on the web at <Neets Module 10-Introduction to Wave Propagation, Transmission Lines, and Antennas>. It comes close to giving this subject a pretty reasonable treatment. A pretty fair intro. It gets to the point on a number of items pretty quickly. I think the modules are $3.00 each. They can be purchased on the web, but probably through the Govt. Printing Office. The whole set of Navy manuals is described at <http://www.tpub.com/content/neets/>.

I've seen that diagram on occasion and it has somewhat baffled me, but at least now I have some insight into what's going on. The most recent occurrence was Carr's fourth edition of "Practical Antennas Handbook". These diagrams all appeared out of nowhere as though they were quite obvious to the reader. I got the book through Amazon and have about 10 days on a 30 day period to return it, which I think I will. Unfortunately, Carr died a few years ago, so there will be no new changes to it.

It is tempting to look at his software CD for the book to see what antenna design tools are on it. I think I'll resist the temptation though. It would be interesting to know what some sort of total package looked like. I'm curious if there's some general design tool, or it's just a bunch of programs for different antennas. It would be interesting to know if one can start from some general set of requirements and the program would lead the designed to the appropriate design.

Dan,

To read the notes again, it is necessary to "go back to the start of program" from the 'results' screen.

The loading coil is always continuous from one end to the other. There are no breaks or cuts in it.

The coax line can have its braid attached directly to the centre of the coil with the inner coaxial conductor tapped into the coil a few turns away from the centre. But this is not recommended.

It is much easier to construct and adjust the number of link-turns by using a link-coupling coil. The link-coupling coil is wound over the top of the center of the main coil and is well insulated from it. You can use the same type of wire for both main and coupling coils.

Close-wound enamelled magnet wire is suitable except at the higher frequencies where not many turns are needed.

With link coupling either coax or balanced-twin feedline can be used. It is easier to change the number of turns on a link coil.

It may be necessary to change the number of turns on the link coil to provide an impedance match with the feedline impedance. The computed number of turns on the link coil is approximate. Only a whole number of turns is possible in practice.

When the feedline is directly tapped into the main coil, a soldering iron and other work is needed to change the number of tap turns.

Don't forget the antenna is a one-frequency, one-band, very narrow bandwidth antenna. To resonate the antenna exactly to a particular frequency it is necesary to prune the length of the loading wires or loading rods at each end of the main coil.

The antenna is easier to construct and adjust for use in a confined space such as an attic, at frequencies between 1.8 and 10 MHz.

Good DX in 2006.

Reg, G4FGQ.

It's a standing-wave antenna. That means there is a forward
wave and a reflected wave. The forward current adds to the
reflected current all up and down the dipole. The magnitude
of the reflected current arriving back at the feedpoint is
approximately 90% of the forward current and are assumed to
be approximately equal by Kraus. The forward current
and reflected current are very close to being in phase at
the feedpoint. The forward and reflected current are equal in
magnitude and 180 degrees out of phase at the tip of the
dipole. The feedpoint impedance of a 1/2WL dipole is approximately
(|Vfor|-|Vref|)/(|Ifor|+|Iref|). The angle of the reflected current
is close to equal in magnitude and opposite in sign to the forward
current at any point along the dipole so the angle of the net
current is very close to zero degrees. The net current pictured
on that web page is a standing current wave with the same basic
shape as in a 1/4WL open-circuit stub.

That current distribution is illustrated in any antenna book,
including Kraus and Balanis. It's also in my 15th edition
ARRL Antenna Book.

Hummmm...Maybe, but I'm having a hard time of thinking
of the uses of a ground to cure said problems... Most
of those problems would seem to be better cured using chokes,
etc. If the problem is fundamental overload to their gear, any
grounding on your end won't cure that.

Reg,

I am running Linux and using dosemu to run the programs. It is probably an issue with the dosemu.

The link-coupling coil is essentially a balun?

I am building a 40 foot 80 meter dipole (limited space). The program predicts about 10 Ohms input impedance and 1.1 'link coupling' turns. Does that imply essentially wrapping one turn on the coil for the coax connection? Can one turn provide enough impedance to match to the coil?

Thanks again - Dan

That is understandable. How much coax between the A probe and the
load, and the B probe and the load... how many degress does this total
electrical length change for a 1% change in frequency? Does that
explain some of the phase sensitivity?

>
>The antenna is a copy from the ARRL handbook. It is a 4 inch segment, a 1 inch

>then 20 Ohms.

Don't you need to measure some "known" loads. Why not try a 50 ohm
load tee'd to a s/c stub (quarter wave at a known frequency) and see
if you get the predictable results at different frequencies around
resonance. Then try two 50 ohm loads in parallel with the stub. (339mm
of RG58C/U should have a Z of around 6000+j0 ohms at around 146MHz, at
half that frequency it should be 0.85+j50, etc...

>
>How can it measure very close to 50 Ohms? Is there something wrong with this
>analysis?

See if you can trust your measurements on known loads before wondering
why the unknown load isn't what you expect when using unknown
measurement technology... too many unknowns.

Hi Owen,

Being very touchy, especially to the specifics of sitting very still,
sounds like classic common mode problems.

If you have an imbalance current trying to find its way to ground, it'll take the path of least resistance (technically, impedance). If that path is the mains wiring, you have a lot of potential for RFI. If you can convince some of that current to go elsewhere by "grounding" your station, you're likely to cut down the RFI. But a better solution is to get those feedline currents balanced so you won't have any imbalance or "ground" current to deal with in the first place. It brings the added benefit of putting the power into your antenna to be radiated rather than being radiated from the conductors carrying the imbalance current.

Radiation from the feedline is usually the least of one's problems.

99 % of RFI is due to radiation from the very nearby antenna.

Yes it does Richard. I saw Roy's response regarding isolation of the
feedline, and it is a valid comment. My comment was towards the
reported frequency sensitivity... until the effect of the propagation
delay is removed from the results, the underlying impedance is
obsured.

Sometimes the improvements to the antenna and feedline are not enough to prevent interference. Also, RF grounding may be ineffective because it's impedance is too high to successfully shunt the ground current away from the mains wiring.

However, there is also a third option: use a series RF choke in the station mains feed. This can have two beneficial effects. It keeps the ground currents out of the mains where they can cause interference, and it can also reduce the incoming common-mode current on the feedline.

A suitable mains choke for the whole station can be made by winding *all* of the mains conductors (live, neutral and safety ground) on a stack of ferrite rings. It's necessary to choke all the mains wires because they are capacitively coupled together at RF. The choke is a high impedance at RF, but the safety ground wire is continuous through the choke. Alternatively you could thread all the wires through a string of large ferrite beads. Of course it's no coincidence that these mains chokes look a lot like the chokes you'd use on a feedline.

An alternative is to use a commercial three-wire mains filter, which has an RF choke in the ground conductor, as well as the normal pi-filter in the power conductors. (I wouldn't recommend a homebrew mains filter. The safety and code compliance issues are better left to full-time

specialists.)

Another essential is to organize the mains wiring of the whole station so that *all* the mains feeds and mains ground connections pass through the RF choke. (This goes along with the established safety recommendation to have one Big Red Switch supplying mains to the whole shack.) If there is a sneak path to ground that doesn't go through the station mains choke, then of course the RF current will take that easier path and the choke will be ineffective.

A clip-on RF current meter is an excellent trouble-shooting tool. There are constructional details on my 'In Practice' pages, and MFJ sell two different ready-made models.

When you have installed a station mains choke and eliminated all sneak ground paths, the RF current meter will show you two things:

1. Without an RF ground, the incoming common-mode currents should be significantly lower than before. In simple terms, common-mode feedline currents cannot enter the shack if you have choked off their exit path to ground.

If you try to look at the situation in more technical detail, there are more unknowns (such as distributed capacitance to ground) than you can accurately identify. That's why RFI is so hard to predict and generalize about. Therefore the best approach is always to *measure* the RF currents on all entering and exiting conductors, before and after each modification you try.

2. An RF ground connection may make the common-mode currents *worse* by providing a path through the station. If that is the case, then don't use an RF ground - it isn't compulsory to have one. (You still have to think about lightning protection, but that most certainly does *not* involve routeing the lightning currents to ground through your shack!)

There are three good articles on RF grounding in the public area of the ARRL website:
http://www.arrl.org/tis/info/grounding.html

No, but I HAVE measured RF current in the antenna - from where most
RFI originates.

Have you ever run 400 watts from an 80 meter 1/2-wave dipole a few
feet above your roof and not far from the TV aerial?

Roy!

Just a legitimate crude guess - perhaps biassed a little in the
opposite direction to the normal excessive bias.

If I remember correctly, you, your very good self, used Eznec to
demonstrate that even under the most adverse worst-case conditions you
could think of, power radiated from the feedline is only a fraction of
that radiated from the antenna.

. . . . . and the equipment being interfered with is in the
near-field of the antenna just as it is in the near-field of the
feedline. That, for most people, includes your next-door neighbors.
Especially if your next-door neighbors happen to be within the antenna
beam.

Reg.

Can't you see the circularity of your own 'logic'? If you haven't measured common-mode RF current in the feedline as well, you don't actually have a clue where the interference is originating. All you have is an unsubstantiated opinion.

>Have you ever run 400 watts from an 80 meter 1/2-wave dipole a few
>feet above your roof and not far from the TV aerial?

I'm not disputing that RFI very often originates from the antenna - of course it does (and the question you pose is a set-up, designed to make *sure* it does).

What I object to is your sweeping generalization that "99 % of RFI is due to radiation from the very nearby antenna." When absolute nonsense is delivered with absolute confidence, some unfortunate beginner might actually believe it.

However, since you asked...

In a typical small British back garden, I have been forced to do something very similar to what you describe. Sure enough, it caused RFI, but the interference was *not* due to my antenna! It was entirely mains-borne, and only to the two neighbours (not the closest) who were connected to the same phase as ourselves. The cause of the interference was that a substantial fraction of my RF ground current was going into the mains ground. Once I'd cleaned up my act and stopped injecting RF current into the mains, the interference stopped too.

The high field strength from my antenna wasn't a problem at all, and the neighbours continued to watch their TVs until I took the antenna down.

That's how it was in that one particular case.... but unlike you, I'm not claiming it represents 99% of anything.

With RFI, the only safe generalization is to keep your mind open to *all* possibilities.

In some cases, that nearby antenna is a counterpoise
laid across the floor which some people consider to
be a "ground" of sorts. :-)

REALLY??

I thought most RFI issues, in today's world, are related to lack of selectivity in the device experiencing the interference. RFI is generally a susceptibility in the interefered with device. Read ALL the information provided and you should find a manufacturer's disclaimer.

If the transmitted signal is 'clean' [meets applicable standards] then the cause of RFI is SUSCEPTIBILITY in devices designed for MAXIMUM profit.

I'm not responsible for susceptibility issues. A neighbor complained that my station was coming through his computer speakers. I invited him to my station and turned on my computer and speakers. At 1 KW output there was/is no RFI in my speakers !!! [My computer is co-located with my station]. I suggested that he contact the manufacturer of the speakers and obtain information to reduce susceptibility. I showed him how I solved the susceptibility issue for my computer. The responsibility is now his.

Have you considered that there may be non-linear effects in the test set up?

The MFJ uses several to ten milliwatts in it's circuitry [+10 dBm].
Sensitivity is generally measured at the pico-watt [~ -130 dBm] level.

Owen

Let me pick a nit or two.

More attenuation is not necessarily better. In theory the improvement
in source match is two times the attenuation, so a 10 dB pad improves
the return loss to no less than 20 dB, even with a zero ohm source,
and with a decent source match of RL = 10 dB or so, is as good as you
need. (I know you know this already)

I say this because it's very likely that the return loss of the
attenuator isn't any better than 25-30 dB, regardless of its
attenuation. For example Narda makes a "precision" Type N attenuator:

http://www.nardamicrowave.com/east/PassiveComponents/pdf/attenuators/FixedPrecision.pdf

Note the VSWR spec, 1.15 at low frequency. That's a 23 dB RL. So although a 20 dB pad in theory provides a minimum 40 dB RL, the actual RL can be as little as 23 dB.

Manufacturers have to work really hard and typically use a precision connector like 3.5mm or 7mm to build a 40 dB RL termination although Anritsu will sell you a 40 dB RL type N termination for -only- $650 USD.

Also, and this goes back a post or two, where you suggested that if a pad is used between the generator and the input to the coupler, the "A" probe (reference/incident) should be between the generator and the pad.

This is contrary to what I tried to recommend earlier when I said:

"It would also be nice it you had a 6 - 10 dB pad between the generator and the directional coupler (DC); located right at the DC. You want the source match to be set right there and the A probe to sample right there."

Let me offer this thought experiment:

If you had two directional couplers, such that one could be used to sample the forward signal and the other the reflected, would you place a pad between them to isolate the generator from the effects of the load?

Still, if the antenna is TRULY balanced (a situation that only rarely
actually happens), you won't get common-mode currents. I've never had a
problem with them with well-grounded (from an RF standpoint) ground-
mounted verticals either.

Essentially this is why I recommend using open wire or twinlead and
feeding it through a proper balanced-line tuner. Years ago, I built an
amplifier that literally had a balanced line output and fed a 600-ohm
feeder direct off two taps on its output coil. That feedline was only
ten feet long and I worked a TON of 80m DX an the inverted vee that it
connected to. And I could always tap the coil so as to have ZERO RF in
the shack (though my landlady's little 7.5 watt light bulbs used to light
on some frequencies when the house wiring picked up direct from the
antenna).

You're right. I didn't catch the polarization thing. In fact, building
them on the same boom would be quite workable.

Is it not true that if the currents on the transmission line are unbalanced (i.e., unequal on the two conductors) then the transmitter must already be connected to ground? If not, what is the path of the differential current?

Chuck

Tim!

I was out of order confusing your design services with baluns. Please accept my apologies. But I did make it clear that CHOKE baluns were involved. You may see elsewhere what a choke balun actually is.

If you already have a balanced tuner then by all means use it. But if you don't have one there's no need to make one or buy one.

It is more convenient to use an ordinary unbalanced tuner plus a very simple to make choke balun which has no particular impedance matching properties apart from being a very short length of transmission line of predictable Zo and predictable phase shift which don't matter very much.

It seems my rhetorical question has inadvertently stirred up quite a discussion the newsgroup.

I wish you much success with Wescott Design Services in 2006.

Reg, just a radio amateur, G4FGQ.

Richard Clark wrote:
"---where dBm is frequently a short hand for dB (re1 mW into 600 Ohms)---."

I agree, but I`ve worked with communicatiobs systems in which the builder specified signal (test-tone) levels throughout in dBm regardless of the impedance at the particular point. Incinvenient, maybe, but often the conversion factor is specified for reading with a dB meter calibrated for 600 Ohms.

dB is a power ratio. dBm is a power level for which the 0 dBm reference is 1 milliwatt. The impedance is not specified. 2 milliwatts is approximately +3 dBm and 1/2 milliwatt is approximately -3 dBm.

The a-c voltmeter which reads in dB is likely calibrated at 600 Ohms impedance. Volts vary as the square root of the power. +6 dB is 4X the power but only double the voltage.

dBm is frequently specified as a test-tone level at various points throughout a communications system. The dB meter will only be correct when the impedance at the measurement point imatches the impedance for which the meter is calibrated. When the impedance is different, The system builder will often give a correction factor to be used with a 600-Ohm dB meter.

Knowing the power level in milliwatts, the a-c volts are easily calculated from the square toot of PR.

Best regards, Richard Harrison, KB5WZI

Danny Boy,

If you are happy with your link-coupled tuner, which can be either balanced or unbalanced, then by all means stick with it. I must admit it is something I forgot about.

Many years back I had a similar commercial tuner. It didn't cover enough bands for me. So I dismantled it. The only parts worth recovering were the slow-motion variable capacitor drives and the nice skirted tuning knobs. Which I still have. They are of sentimental value.

Ever since then I have used only home-brewed tuners with coils and capacitors connected with universal alligator clips. But never of the balanced variety.

I wish you the very best of DX for 2006.

Reg, G4FGQ.

For an unloaded Q of 50, I would shoot for a loaded Q of around 5. If you
plan to put any power through this, try getting the unloaded Q up to around
200, with a loaded Q of around 8.

My guess is that if you remove the 4.7K, the impedance at the other end of
the network will not change all that much.

134. Re: Why ground the transmitter?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-03 19:29:21 UTC
From: nm5k@wt.net
Message-ID: <1136316561.623906.5570@f14g2000cwb.googlegroups.com>
Source record: 65695

If you have an imbalance current trying to find its way to ground,
it'll
take the path of least resistance (technically, impedance). If that
path
is the mains wiring, you have a lot of potential for RFI. If you can
convince some of that current to go elsewhere by "grounding" your
station, you're likely to cut down the RFI. But a better solution is to
get those feedline currents balanced so you won't have any imbalance or
"ground" current to deal with in the first place. It brings the added
benefit of putting the power into your antenna to be radiated rather
than being radiated from the conductors carrying the imbalance current.

Exactly. This is why I call the "grounding" method a bandaid.
I think the 2nd solution is the best route to go. And if you use
the 2nd solution, the length of the line, and the location or height
above ground will not matter. And no worrying about getting a
good rf ground, which is hard to do in many remote locations of
a building.

Source record: 65696

MK,
The 'problem' wasn't completely on my end (neighbor's defective devices), but a good grounding did help cure the a RFI. Is grounding a 'sure thing' as a cure? Nope, but it certainly doesn't hurt if it's at all possible, which isn't always a 'sure thing'.
Also used to use a fence around the place as a ground. Very BAD idea since the fence was connected to the neighbor's fence too. Just 'took' the RF closer to the neighbor, probably a 'sort' of direct connection to his 'stuff'. Always a 'bad' idea? No, but something to think about.
'Doc

136. Re: Still have problems reading MJF-269 Analyzer

Source record: 65697

Hi,

A little obvious perhaps but have you tried a 50-ohm resistor across the output of the 269 to check its calibration. I have a 259B and will wind a similar inductor to see what results that network yields. I did a SPICE run on your values and it came up with figures within the correct range although phase resonance and maximum impedance were off by a MHz or so.

Will report back - Joe

>load?

No, of course not... it just adds another source of error, and
increases the gap between the measurements being made on both probes.

But Dan does not have two directional couplers. To my mind, if the A
probe is sampling the main transmission line, the sample is of the
resultant of the algebraic sum of the forward and reflected waves
rather than a sample of the forward wave alone (well, nearly alone) as
you would get with a directional coupler. My suggestion of placing the
A probe on the source side of the attenuator is to reduce the
contribution of the reflected wave to the A probe measurement. The
attenuator was proposed mainly for isolation of the forward wave
component for measurement, rather than a source matching issue...
which also exists.

Have I got this wrong?

All comments on practical limits of RL from pads / attenuators noted,
and understood.

Reg, it would really be nice if you could come up with some new topics to keep you entertained on those dull evenings. You brought that one up just four months ago. Maybe you can keep a list of your favorites, noting when you used each one the last time, and giving us a little longer break between repetitions.

Reg Edwards wrote:

> that radiated from the antenna.

Sorry, you don't remember correctly. I said on quite a number of occasions (and you once even agreed) that you can't assign radiated powers from different parts of an antenna system. It was actually kind of sad -- you kept loudly demanding that I provide fractions of power from the feedline and antenna, ignoring my statements that it couldn't be apportioned that way, and some time later you said out of the blue that it couldn't. And then you wrote a program that does just that. At the end of this posting is a summary of your contradictory statements which I originally posted here on Sept. 1.

I did find with EZNEC that the current on a feedline could be very much larger than your program predicts.

> . . . . . and the equipment being interfered with is in the
> near-field of the antenna just as it is in the near-field of the

> Especially if your next-door neighbors happen to be within the antenna
> beam.

Depends on the orientation of your antenna and the size of your lot. My antennas are some distance from the house, but the feedlines come right inside.

----- My posting on this group on 9-1-2005 -----

If anyone besides me is having trouble keeping track of what Reg is trying to say, maybe the following recent quotes will help. That is, they'll help you understand why you're having trouble keeping track.

For what it's worth, I agree with the first quotation of 8/31. But apparently Reg doesn't, even though he said it.

Roy Lewallen, W7EL

8/30:

Perhaps somebody might be prepared to state the power actually radiated from feedlines in watts. At least it may create the impression you know what you are talking about.

8/30:

Roy, do everybody a favour, by stating, numerically, how much power is radiated from feedlines. Then somebody might have some confidence in what you are bafflegabbing about.

8/31:

Any current which finds its way on to (3), which ought to flow in the antenna, will result in the coax participating in the radiation pattern of the whole antenna structure.

BUT IT IS A SILLY QUESTION TO ASK HOW MANY WATTS ARE RADIATED FROM THE FEEDLINE.

OR, CONVERSELY, HOW MANY MICROWATTS ARE PICKED UP BY THE FEEDLINE ON RECEIVE.

The feedline cannot be treated in isolation as if it behaves independently of the antenna. For starters, the radiation resistances of the feedline and antenna do not add arithmetically. They interact with each other.

8/31:

If you erect a 10 meter 1/2-wave dipole and center-feed it with a 50 feet length of coax, and then transmit on 1.9 MHz, 99.9 percent of available power will be radiated from the feedline and only 0.1 percent from the antenna itself.

http://www.smeter.net/feeding/feedpowr.php:

Centre-Fed Dipole - Radiation from Coaxial Feedline
Author: R.J.Edwards G4FGQ ï¿½ 25th March 2003

Program Notes
. . .
With no loss in accuracy, to simplify the model, the transmitter is located at the dipole centre and the coaxial line is replaced by a single conductor of the same diameter as the coaxial braid. There are 3 radiating elements. Radiation resistance, input impedance, and input current of each element is calculated. Finally, the percent of total power radiated by each of the three elements is calculated.

> actually happens), you won't get common-mode currents.

That's true only if by "balanced" you mean that the two feedline conductors carry equal and opposite currents. In that case, common mode current is zero by definition. But if you really mean symmetrical, as most amateurs do when they say "balanced", you certainly can have common mode current.

A detailed explanation of how that happens is in the article at http://eznec.com/Amateur/Articles/Baluns.pdf, and the article by Walt Maxwell, W2DU at http://www.w2du/r2ch21.pdf which is referenced at the end of the first article? Note particularly figures 3 and 4 of the Baluns.pdf article.

> I've never had a
> problem with them with well-grounded (from an RF standpoint) ground-
> mounted verticals either.

The reason this provides balanced feedline currents is that the impedance to ground at the base of the antenna is much less than the impedance looking back from the feedpoint down along the outside of the feedline. Consequently, the large majority of the current from the inside of the coax shield flows to ground rather than down the outside of the coax. And laying the coax on the ground keeps coupled common mode current down.

>
> Essentially this is why I recommend using open wire or twinlead and
> feeding it through a proper balanced-line tuner.

That combination will produce a truly balanced system with no common mode current. But it's not the only way.

Your thinking is correct. If you had a small, battery operated rig, you could theoretically force current balance by completely isolating it from ground. You might burn yourself when you touch it, though.

In practice, differential current can flow to ground via capacitive coupling from the rig to ground, or by flowing onto any connecting wires such as power supply, speaker, or key leads, which will radiate.

Common mode feedline current is generally sinusoidally distributed. So you can have a relatively small common mode current at the rig but a much larger one at places on the feedline, if the rig happens to fall at a common mode current node. When the current is due to coupling, a single balun will be ineffective if placed at a natural current node, or in some other cases will only change the distribution by moving the node, rather than reducing the overall current. In those cases, two baluns placed about a quarter wavelength apart are effective.

Amos,

The circuit is passive (R/L/C) only. I would not expect any non-linearity.

I suspect the previous post may have been correct. The match was over a large ratio of impedance (50 Ohms to 4500 Ohms). I expect the small value of inductor and reasonably low Q was limiting the performance of the circuit.

I tried the match again from 50 Ohms to 800 Ohms as a test and found the MJ-269 showed match efficiency of 90% with SWR dropping to 1.8. These results are much better.

Regards

David

Hi de KJ4UO,

I have a MFJ-269 and I measured a value of 65 and j16 for my 6-meter dipole, the dipole is a little long so I assume that the j16 is inductive and I need to add a cap of equal reactive value.
Also, The measurement was taken directly at the antenna feedpoint without any coax.

Once I back calculate the cap value ,should I place this cap across the antenna input at the feed point or in series with the signal line of the feed point to cancel out the j16 and leave me with 65 ohm resistive?

tnx de KJ4UO

Tam,

I believe you are correct. The 147nH inductor is the largest "can" that
I have. The inductor really needs to be larger to get the loaded Q of
the match down for this ration of impedance transform.

When trying 50 Ohms to 800 Ohms (instead of the original 4500 Ohms), the
match works. The actual loaded Q was about 8.

Seems a good rule of thumb would be to go for loaded Q around 10% of
unloaded Q.

Thanks

Adding a cap with 16 ohms reactance in series will bring your impedance
to 65 ohms resistive. Adding a 280 ohm reactance cap in parallel will
cancel the inductance but the resistive component will now be about 69 ohms.

Why not just trim the dipole a bit?

How about that? I read further into the book and found a whole chapter on the software on the CD. Another quick romp through the book tells me that (I'm inferring this.) that what most of it is about is describing antennas and where they might be used. It looks like a potential catalog of such designs to try out on the software. I don't think that's necessarily the reason why the book was written, but it makes it appealing. I don't see anywhere that all the designs offered could be investigated with the software on the CD.

Roy, perhaps you have an answer for the last statement. I see that one of your programs is included.

How did you keep your body from affecting the measurement?
Why do you think an SWR of 1.5:1 is enough to worry about?

> Once I back calculate the cap value ,should I place this cap across the
> antenna input at the feed point or in series with the signal line of
> the feed point to cancel out the j16 and leave me with 65 ohm

The impedance displayed by the MFJ-269 is a series impedance.
If the feedpoint impedance is indeed 65+j16, two caps of -j8,
one to each side of the dipole on the antenna side of a 1:1
choke-balun will tend to keep the currents balanced.

But here's another approach for your consideration. A little
less than 1/2WL of 300 ohm or 450 ohm line will bring the antenna
to resonance, assuming a 65+j16 feedpoint impedance. That's about
8.5 feet on 6m. A series section of ladder-line is usually easier
to install than discrete components. And if you did make an error
in your measurement, trimming the ladder-line to resonance is a
pretty easy task.

OK, if we're still talking about one vertically polarized and one
horizontally polarized, I'd slap'em together so that the vertical
elements are at least 1/4 wavelength from the horizontal's boom.

Or, you could do what some fellers seem to do: Spend all your time in
rraa, anguishing and arguing about antenna installation choices. After
all, which propagates best: The antenna on the floor of the garage, or the
one up in the air? HI!HI!

JONESY'S AXIOM:
You never put an antenna up just once.

Good Luck and Happy New Year!

There's no point in adding a capacitor at all. Assuming you're using a 50 ohm feedline, it would only change the SWR from about 1.5 to 1.3. I can't see where that would be worth the trouble.

But you haven't measured the dipole impedance. One terminal of the MFJ-269 is connected to one side of the dipole. The other terminal is connected to the dipole in parallel with the outside of the MFJ-269 itself and, if you were holding it, your body also. So you're measuring the impedance of an antenna having a wire for one leg, and a combination of a wire, box, and body for the other.

If you really had measured the dipole impedance and if the reactance was enough to bother with, the answer to your question would be to put it in series.

I use my 500+ foot horizontal loop on 6 and 2 meters with homebrew
balanced tuners from the '63 ARRL Handbook. On HF a balanced double-L
tuner does the trick. The balanced-L tuner does use a balun but it is
between the rig and the matching device. The only problem with using
the Johnson Matchbox is 30M

Sorry, I know nothing of the book, except I vaguely recall Joe
mentioning that he was including the EZNEC demo program with a book.

If you're interested in modeling various antenna designs, consider the
ARRL Antenna Book. On its CD are several hundred EZNEC models of
various antennas discussed in the book, plus a special version of EZNEC
which can be used to analyze them (http://eznec.com/eznec_arrl.htm). The
Antenna Book models can also be used with any standard (non-demo)
version of EZNEC.

Source record: 65713

David,

With an MFJ-259B I just ran a test using an air-wound coil resonating with a series combination of 820pF and 100pF at about 44MHz, all strapped across a 4.7K resistor. The figures came out as follows -

Inductor (calculated) = 146nH

Real part of Zin (with 4.7k) = 14 ohms (tuned for X = 0)

With perfect components, and the capacitor tap chosen, this should have been 55 ohms. Disconnecting the 4.7k (again tuned for X = 0) the real part of Zin increased to 20 ohms. This, if my maths are correct, means the inductor's equivalent shunt loss resistance was about 1.6K giving an inductor Q of around 40.

Due to the similarity of component values used, these then are the sort of figures you should have obtained. Obviously the limiting factor here is the circuit Q but I supposed you had intentionally chosen this to meet a specific bandwidth target.

Cheers - Joe

I bought a used A99 a figured I would give it to my brother to put up in his attic. so he monted the antenna on a PVC mast that he made in the 20' tall attic. It was a 1.5 (SWR) 1 & 40. My father decided to play with it and now it is showing infinity on both 1 & 40 turning the rings changes little it never drops below 3.0. can someone tell me the correct way to tune the antenna (this way I can make sure I am doing everything right) also does the antenna need to be grounded by anything other then coax (ie a ground strap to cold water pipe or something alont them lines)... please help

Sofar all the answers are assuming the question is will one antenna affect
the other antenna. One other thing to look at is will the transmitter
'kill' the receiver of the other rig ?

Roy quite reasonably wrote, "If you really had measured the dipole impedance and if the reactance was enough to bother with, the answer to your question would be to put it in series."

You can instead put capacitance in parallel with the nominal 65+j16 (if that's what it is) to make it non-reactive, though doing so will raise the resistive impedance, and thus not improve the SWR rel. to 50 ohms as much as series capacitance (a pair of balanced caps...). But if you increase the shunt capacitance beyond what's needed to cancel the reactance, and then add series inductance, you can get to a "perfect" match to 50 ohms. (There are, in general, many ways to match one impedance to another, by using various combinations of inductance, capacitance, transmission line stubs and transmission line series sections.)

But first beware of the pitfalls Roy mentioned, and understand if you really need additional matching.

Cheers,
Tom

Motorola 900 Mhz Canopys are advertised as "non line of site", so you
may get more mileage than you'd expect when running at this relatively
low frequency. If you are looking at paths that can be well defined,
try a program called "Radio Mobile" for a very good simulation of the
situation. It is freeware, and the databases it uses are also free
(courtesy of the US taxpayer and some hardworking US Shuttle astronauts
and groundcrew).

Message-ID: <nzFuf.167791$V7.17075@news-server.bigpond.net.au>
Source record: 65719

Hi,

I have a design for a Yagi antenna at 436MHz and would like to scale it to 921 MHz. The calculations I used from the understanding I have obtained from reading various articles appears below.

Would someone be kind enough to advise me if this procedure and values look correct ?

Thanks in advance.

The original dimensions(mm) were

Boom = 15 or 20mm square aluminum, 350mm long

Element Length Spacing Diameter
RE 336 0 8
DE 316 80 10
D1 300 190 8
D2 292 330 8

My scaled values to 921MHz
Boom = 12mm x 12mm aluminum 166mm long

Element Length Spacing Diameter
RE 158.9 0 3.78
DE 149.5 38 4.73
D1 141.9 90 3.78
D2 138.2 142 3.78

Now I scaled the tubing to 6mm diameter that I have in stock
Element Length Spacing Diameter
RE 158.5 0 6
DE 148.7 38 6
D1 139.4 90 6
D2 135.3 142 6

Regards

David Huisman

Suspending the analyzer might be adequate for 6 meters, which is the antenna under discussion. But I should mention for the benefit of the general audience that it isn't adequate for 2 meters. Not too long ago I heard from an EZNEC user who found a substantial difference between modeled and measured results from a simple antenna. On my suggestion, he added a simple wire frame representation of the MFJ 269 to his model, and it made the model results much closer to his measurement. So in that case the antenna analyzer itself was enough to substantially skew the measurement.

Are these through the boom, and if so, insulated, or uninsulated?

If not through the boom, give specifics on the mounting.

Please do this for both the original antenna, and how you propose to build the scaled one.

The elements are mounted approximately 3mm off the boom by nylon
insulator blocks on the original design.

The scaled design will use same construction.

Reg wrote, "Try suspending the measuring instrument in mid-air to remove your body capacitance and see if it makes any difference to the measured impedance."

Even better (perhaps), set up the antenna as you plan to use it, including balun and feedline. Make your measurements at the "other" (non-antenna) end of the feedline. Back out the effects of that length of feedline, and you have the antenna feedpoint impedance in that particular environment. If the line is reasonably long so you and your measurement device are at least a couple wavelengths from the antenna, and reasonably well decoupled from the antenna so that there isn't a lot of "antenna current" on the feedline, your measurements should be essentially independent of your presence and the presence of the analyzer.

Cheers,
Tom

Hi again all,

the dipole was suspensed on a pole and the MFJ-269 was connected to it, no body effects here. After adjusting frequency then I move away from the setup.

I do understand that 65 + j16 is not really a bad match, if I did add a capacitive reactance, then would I have to place two caps, each of equal value in series with coax?

If I wanted to do a shunt capacitor, would I find the admittance of the above and then determine a shunt from the resulting reactance?

The Autec Analyser is a better instrument than the MFJ for
suspended-in-mid-air measurements. It is much smaller and is lighter
in weight and has a smaller capacitance.

The Autec case has a self-capacitance of the order of 3 pF
corresponding to a reactance of 1768 ohms at 30 MHz which can be
ignored when measuring 50 ohms with zero lead length.

The Autec's highest frequency is 35 MHz.

The MFJ's highest frequency is at VHF. With a self-capacitance of 7
pF at VHF substantial errors can occur.

To estimate capacitance, the DC capacitance of a sphere is -

pF = 55.55 * Diameter in metres.

Hi again all,

the dipole was suspensed on a pole and the MFJ-269 was connected to it, no body effects here. After adjusting frequency then I move away from the setup.

I do understand that 65 + j16 is not really a bad match, if I did add a capacitive reactance, then would I have to place two caps, each of equal value in series with coax?

If I wanted to do a shunt capacitor, would I find the admittance of the above and then determine a shunt from the resulting reactance?

Thanks,

I went back through the calibration procedure.

1. The meter appears to be performing as it is supposed to. The 'static readings work repeatably and predictably. With a balanced configuration shorts and opens read correctly.

2. The pad I was using appears to have a frequency shift. With the 'legs balanced for length' the measurement would change with frequency. This really confused the measurement process. I put it aside.

3. I have some 23 Ohm couplers. These of course confuse readings when used as normal couplers. However if they are used in a truly balanced configuration - that is the legs are configured as close to identical as possible then they appear to work.

I am going to shelve this until I find or make a 50 Ohm bi-directional coupler.

Thanks again - Dan

The basic principle of scaling antennas according to wavelength is that you must make an *exact* scale model. That means scaling every dimension, and not adding any new or different 'features'.

Often that isn't practical for mechanical engineering reasons, so then you need to apply corrections. However, you should still aim to keep those corrections as small as possible. For example, simple scaling is likely to produce odd, unavailable values for the element diameter, so it's OK to use corrections to change to the nearest commercially available diameter. But if you also decide to double the diameter, the correction is more risky - you're entering the territory of a completely new design.

Sorry that I don't have time to check your particular dimensions in detail, David, but you can find resources for scaling and constructional techniques on my 'VHF/UHF Long Yagi Workshop' pages. There is a downloadable program which leads you through the relevant questions, and also a link to an online Javascript version.

(From about 1200utc I will not have access to this newsgroup for the next few days, so I hope the above will keep you going.)

Tom Ring wrote:
"Motorola 900 MHz Canopys are advertised as "non line of sight"... so you may get more mileage than you`d expect when running at the relatively low frequency."

It`s true that radio does not always take a direct path. Part of ham radio fun is in anomalous propagation. It`s also true that the higher the frequency, the smaller the obstruction that can block propagation.

900 MHz is more reliable than frequencies in the GHz. A point to multipoint system may require more reliability than a single point to point system, and more reliability than: "Can You believe it? I`ve contacted DX!" I`ve engineered and installed several 900 MHz systems which proved to provide, with their path clearances and fade margins, 24-7 reliability of very nearly 100%.

Line of sight is defined as: "The distance to the horizon from an elevated point, including the effects of atmospheric refraction." Another definition is: "The propagation characteristic of microwave radio."

900 MHz is on the border between UHF and microwaves. It shares some of the characteristics of both.

Best regards, Richard Harrison, KB5WZI

David,

The inductor loss is (LoadedQ)/(UnloadedQ). So for your numbers of 26 and 50, the loss will be 0.52, or about 3 DB. I think you will want to look at a different configuration. Either something that puts a very small cap in series with the 4500w||2.5PF, or go for something like a 2 uH inductor in parallel with it. At 45 MHz you need an LC product of 12.5 to resonate; this will then be inductive. Tune and match off a tap of the inductor with 2 capacitors.

Tam

To keep things balanced, it would be best to split the series capacitance into two parts. They should be -j32 ohms each, as they are effectively in series: 200pF (or 180 or 220) in each leg. It wouldn't be the end of your world if you used a single 100pF cap, though.

Yes; convert to admittance and parallel a capacitive suseptance to cancel the reactive part, about 11pF. Or as I suggested before, put more capacitance in parallel with the feedpoint and add series inductance: 38pF shunt and a pair of 47nH inductors, one in series with each leg between the feedpoint and the feedline, will get you very close to 50 ohms resistive from the stated 65+j16 at 50-54MHz. (I assume the antenna doesn't stay at that impedance over the whole band, though.)

Cheers,
Tom

180. Transmission Line Reflections

It seems reasonable that if I have an open ended transmission line that the current would reflect back and change phase. After all, the electrons at the end have nowhere to go but back down the line. However, the voltage is a different matter. There is no phase reversal (or polarization change) There doesn't seem to be an intuitive reason for this. However, if one examines the equations for current and capacitive voltage, then it falls out of the math. Still, where is the non-math that indicates this is true?

Now suppose instead the line is short circuited. The voltage returns down the line, and the current does not. In this case, there doesn't seem to be any non-math or intuitive feel for why the short should cause this--either for voltage or current. Can one clue me in on what's really happening above (voltage) and here (voltage and current)? Inquiring minds want to know.

Firstly, thanks for posting AN 77-3, it is a long time since I read it, and have little recollection of the recommended low frequency test setup.

The HP 11549A is described as a power splitter, so I am guessing that it is some kind of hybrid (ie as in hybrid transformer) that in that role, whilst splitting the power to the "output" ports, will prevent power flow between "output" ports, so isolating the A probe to some extent from the reflected wave on the unknown load side.

Additionally, the 8491 attenuator in the load path will improve the return loss at the B side 11549A port, so that combination seems to be stabilising the loads presented to the splitter (which if it is a hybrid, improves is cross port isolation), and improving the RL by the action of the attenuator and splitter.

Without knowing the loss in the 8491 (I know they were available in 10dB, but I think there were -3, -6, -10 and -20s), or the isolation across the splitter, it is hard to quantify the total isolation of reflected wave from the A probe.

It may be that Dan should consider constructing a hybrid or Return Loss Bridge, whatever you want to call it, it will be cheaper and have less loss that a dual directional coupler for HF measurements. IIRC, the ARRL has some simple designs.

That's not true. Both are totally reflected.

The math is dictated by the boundary conditions, and those can be used to gain an intuitive feel for what's happening. When both forward and reflected waves are present, the voltage and current at any point on the line are the sum of the forward and reverse waves. When the line is open circuited, the current at the end of the line is of course zero. So the sum of the forward and reverse current wave is zero at the end, and the only way that can be is for the forward and reverse waves to be equal in magnitude and out of phase. Likewise, when the line is shorted, the voltage is zero, and the only way that can happen is for the reverse voltage wave to be equal in magnitude and opposite in phase to the forward voltage wave.

Some confusion can result when discussing the reverse wave. The reverse current wave can be, and usually is, defined as positive in the same direction as the forward wave. If you use this definition, the current changes phase at a shorted end, since the sum of the two current waves has to equal zero when both are defined as being positive in the same direction. However, you can also say that the current simply reverses direction and remains the same in phase. Those two viewpoints are equivalent. I've been using, and will continue to use, the convention that the direction of positive current is toward the load for both waves, for this discussion.

At an open end, the forward and reverse voltages are equal and in phase, and at a shorted end, the forward and reverse currents are equal and in

phase. This can be seen by realizing that the voltage/current ratio of the forward wave is the same as for the reverse wave -- both equal the line Z0, but because of the current convention, the sign of the current reverses for the reflected wave. So we know that Vf/If = -Vr/Ir, where If and Ir are defined as positive when flowing toward the load. Now let's apply what we know about shorted ends to find what happens at an open end. At an open end, we know that If = -Ir. Since Vf/If = -Vr/Ir, it follows that Vr = Vf. Likewise, at an open end, we know that Vf = -Vr, so from the same equation If = Ir.

Thanks for the response. Why is any wave reflected at all? In the open case, I can easily visualize the electrons (drifting cloud) having nowhere to go when they reach the end of the line, so the current literally has to go in reverse. Perhaps the shorted line represents a reactive circuit to the incident wave?

Yes, this makes sense that one can deduce the result from the boundary conditions. I'll stop here for the moment until I understand the answer to the question above.

W. Watson wrote:
"It seems reasonable that if I have an open ended transmission line that the current would reflect back and change phase."

That`s about what happens. In fact, the incident and reflected waves at an open circuit have voltages of the same phase and magnitudes. These correspond to a reflection coefficient of 1 on an angle of zero. The result is a doubling of the incident value of voltage at the open circuit. I recall this being called "the Ferranti effect".

It stands to reason that energy is not created or destroyed but the ebergy associated with the H-field must go somewhere when the current stops. The only place it can go is into the E-field, so this accounts for the instantaneous voltage doubling at the open circuit. The current reverses direction and its incident and reflected values add to zero at the open end of the line.

When either voltage or current has a phase reversal, but not both are reversed, a reversal of wave travel direction is indicated. The same thing happens at a short circuit but it is the voltages which add to zero, indicating its phase reversal at the short.

When both current and voltage are reversed in phase, no change in travel direction is indicated as this happens regularly in the cycle of the wave.

Best regards, Richard Harrison, KB5WZI

I believe this is a good test and conclusion. I can only add two small things.

1- the impedance gets further from 50 ohms, the 269 MFJ (Mine has this characteristic) shows more and more error. Try paralleling four 50 ohm loads (with your Tees) or measuring a good 200 ohm load. The 269 shows considerable imaginary at 4:1 real (:-(I think I have heard that the 259 is better.

2- The constant reference to the "pin" being much less than a 1/4 wave is not the correct focus. It is the impedance (primarily inductance in this case) which is the factor of interest relative to the frequency. What's that old rule of thumb? One nano Henry per inch?? One nano Henry per 1/10 inch... Been off that bench too long.

On street wheels the nuts do support torque, but not like a single central
one would (like the formula 1 without the pegs). The holes in the wheel are
tapered, the nut seats on the taper and the lug shaft (threaded lug) does
not contact the wheel hole. The torque is transferred by radial forces on
the nuts. (pardon any unintended pun)

>
> I'm curious.

Short answers:

Worry - Probably not

Intermodulation - No.

Really long answer...

Not sure what you mean by "vibration frequency".

Here's the logic for what is called "Environmental Desensitization", or
"Environmental Desense" for short...sort of.

The type of transmitter is not important for this discussion.

The antenna produces an RF field around it and the vehicle (the desired
effect since it extends out to infinity).

Any conductor relatively near the vehicle or a conducting part of the
vehicle (call it a parasitic conductor or "PC" for short) will have RF
currents flowing in them as a result of the transmitter (this occurs whether
it is near or not - actually the distance only affects the strength of the
current, but for close spacing, the effect is easier to see & understand).

More simply stated: "Everything in the world is a receiving antenna."

The strength and relative phase of the current in the PC (compared to the
transmitted signal) will depend on many things (distance to main antenna,
shape, size, orientation, frequency, other objects and conductivity)

These PC RF currents will also produce an RF field in the region (around the
PC and vehicle). It is no different than the intentional transmitting
antenna except it is not cut to a desired length and shape, but accidental.

The PC RF field(s) will sum with the field from the transmitting antenna
thus producing a slightly modified field - I'll call the "Sum-Field".

The actual "Sum_Field" amplitude and phase depends on the relative strength and phase of the two fields at any point and is therefore complex. These fields sum in a vector addition manner. Sounds all pretty random up to here...

However, we can say for sure that:

If the current in the PC changes, the resulting "Sum-Field" will change.

If the position of the PC changes, the current in the PC will change.

If the size of the PC changes due to an intermittent connection with another near-by PC, the current in the PC will change.

And we know that:

If the PC current changes, the resulting PC field will change.

And most certainly

If the PC field changes, the "Sum-Field" will change.

Keeping in mind that:

A receiver near or far away will receive the "Sum-Field" at its location.

This means that if we have a conductor near the transmitter that, due to any of the above changes, it can "modulate" the field in some way. The modulation must have some relation to the change causing it. It will indeed contain the same characteristic that causes the changing current / field. Therefore, the "modulation" will have the same characteristic as the original change, and it will most certainly contain that vibration frequency or the noise which is the intermittent contact.

So, the bottom line is that the vibration (or noisy contact) will modulate the signal at the receiver. This modulation must most certainly be a combination of amplitude and phase modulation.

This effect is there and usually small enough to be unnoticeable, therefore it is of little to no concern most of the time. It can be the cause of noise in a mobile instillation from things like tail pipe vibration, hood (bonnet) hinges and latch and the like.

P.S. this same argument explains how directional antennas work, such as the common Yagi-Uda and all phased arrays whether parasitic or driven (phased).

73, Steve, K9DCI

P.S. The Apollo recovery and communication ships had this problem due to the High power HF transmitters causing RF current in the Deck railing chains which caused noise sidebands which extended up into the microwave frequencies interfering with the radars...believe it or not - don't know if this is on the web, but I have the NASA papers somewhere.

193. Re: Scaling of Yagi design

And, consider: even then, It might not work as it does on another
frequency. Have a friend (this years ago), who modeled the Komosko-
Johnson yagi for 2 meters (a 13 el, antenna , that was emperically
designed), long before modeling programs, and then antenna range
measured. This was a staple of the old VHF handbooks, and the
ARRL handbooks for years, and seemed to deliver exceptional results.
He had pull at his local company (not to name them)! and had an
EXACT copy made for 1296, and then entered it into a antenna contest-
it failed misserably! (this not only was element length/Dia, spaceing,
,but BOOM diameter/length)!! It was (and is) a work of ART,
but it wont make his retirement check (or Contest Score)
any higher! For those that
wish to try it- look for those names, or for W2NLY-W6QKI in the
ARRL handbooks mentioned. But it must leave to the builder one
of the following conclusions: 1) It was great on 144, but a dog
on 1296, or: 2) It wasn't the greatest design , for even 144 (tho
it compairs favorable with the range patterns that were shown
in the VHF handbook, for 144)! As info, Jim NN7K

Answer-- Don't worry about it! tho, during WWII, there was
the use of a "WOBBULATOR" in some 450 MHz airborn , Friend
or Foe radio sets, these were pre- crystal, P.L.L. type
radios, Broad as a barn (kinda like tuneing a Grid Dip
oscillator to a fm freq, and then YELLING at it-- it will
fm it, but, it won't be reliable for communications)!
But, with todays technology , you will get more phase flutter
from multipath than anything else! Jim NN7K

Jim,

Thanks for your input of caution.

I'm sure that along with all the horror stories there are a multitude of success stories.

My belief is that antennas have been around for years and millions have been constructed on almost every frequency imaginable.

In my case I am new to antenna design and green when it comes to determining the parameters that would best suit my applications.

My requirements are not critical with regard to front/back ratio or the last drop of gain available for a specific design.

I find there are always such a range of responses to a request.
Some of these are the theorists that love to explain how black holes in the universe some 10 million light years away might effect free electrons floating on the end of a copper wire.

Then we have the ones that are not particularly experienced but like to have a say on every topic. They would normally ask why you want it in the first place. "Oh, you want blue, why not have red".

Between these extremes are a bunch of very kind people who have "played" with antennas and gained practical experience that they are prepared to pass on to others.

Modeling programs have come a long way and my understanding is that as long as you model the unit correctly, your actual results should not be too far off. (I don't know how to model yet so hence the reason to ask for help).

I imagine there are still some disasters when engineers build new cars but I believe this would mainly occur when something is overlooked or they are trying to achieve something new.

I am not trying to break any new ground here, just looking for around 7 dBi gain from a Yagi at 921MHz.

Regards

David Huisman

When properly done, I have never had a scaled design fail to perform as expected. I have done several dozen. The designs were 144, 220, 222, and 432 as source and destination.

I don't expect this one will surprise me as to how it performs, especially as it is insulated above the boom.

And, except for the K1FO designs, the VHF handbook contains one of the worst collections of yagis ever assembled. They are at least as bad as the Cushcraft VHF/UHF yagis that had the dual reflectors.

That's what I expected from people who have practical experience and
understand the principles (much better than I current do).

I managed to track down thinner aluminum rod that is much closer to
scaled values of elements in the original design.

The values should be 3.78mm and I can get 3.175mm
For the 4.73mm , I can get 4.763mm.

This should now be close enough to only require small trim in length
to compensate for small change in diameter.

The diameter ratio would be fine given the first diameter you listed.
The others would be fine also. Just specify what you want to use.

Tom,

I have heaps of 6mm in stock. The smaller diameter has to be ordered specially and is more expensive.

So:

Frequency 921 MHz. (20MHz BW or more would be good).

Gain >= 7dBi

F/B ratio not critical.

4 Element Yagi - input impedance of around 29 Ohms (can easily match with 2 par 75 Ohm 1/4 wave section).

Unit to be operated vertically orientated at height greater than 2m.

Element diameters 6mm

Boom is 12mm square aluminium. Elements mounted 3-5mm above boom on nylon insulator block.

Just need accurate lengths and spacing now.

201. Stupid question on twin feedline (air)

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-05 04:14:45 UTC
From: jawod <jawod@fuse.net>
Message-ID: <71286$43bc9d37$42a1bfc2$1899@FUSE.NET>
Source record: 65662

I will assume that balanced (air) feedline is homebrew. What recommendations are there for spacing between the twin lines? Number of spacers per foot? If homebrew, how to keep spacers from migrating...will small wire "stays" modify feedline characteristics?

This is all about feedline to simple dipole or inverted V.

Thanks,

a new (old) ham

jawod aka john

Well, I looked at some physics books that I have access to, Waves by Crawford, in particular. He spends an entire chapter, called Reflections(!), and seems to hit every aspect of how all this works in every conceivable circumstance. One somewhat length section deals with transmission between different media using a variety of explanations using dash pots, strings, and so on. He gets all this out of the way by developing reflection coefficients and other tools, including some boundary analysis, I believe. Then in about 2-3 pages dispenses with transmission lines by looking at boundary conditions using what was developed earlier. This is non-trivial material, and would likely takes many pages of explanation and diagrams to reduce it to a simpler form.

I think I'll pass on going any further with my question via this thread. I can probably drag out enough satisfactory info on this from the book and a few other sources to keep me happy. We could develop a very long thread otherwise. Nevertheless, thanks for your interest and insights via shedding some light on boundary conditions.

Wayne Watson wrote:
"The voltage returns down the line, and the current does not."

What happens on reflection is that either the phase of the current is reversed with an open circuit, or the phase of the voltage is reversed with a short circuit, in the event of a complete reflection from an open or a short. In either case, there is a reversal in phase of only one of the components of the electromagnetic wave, not both. However, the total wave is reflected.

A transverse electromagnetic wave consists of two components, an electric field and a magnetic field. An incident wave has both parts in-phase until it is reflected.

A reflected wave has its two parts 180-degrees out-of-phase upon its first reflection. This fact is how the directional coupler in the Bird Wattmeter distinguishes between the waves traveling in opposite directions through the wattmeter.

Both voltage and current return upon reflection. The difference is zero phase difference in one direction, and 180-degrees difference in the opposite direction.

Best regards, Richard Harrison, KB5WZI

I bought 600 ohm feedline (and dipole) from W7**.
He uses pieces of PVC pipe with notches in the ends
and insulated wires. The notches provide a friction fit on
the wires. Note that you need to be certain that the
PVC has very high resistance at RF frequencies. I
have been told that some do not. You can tell if you
run higher power and the insulators heat up.

You can also buy "ladderline" with 450 or 300 ohm
impedances from a number of sources.

If you can support the center of the dipole, weight is not
as much concern as if you cannot support it. With too heavy
a ladder line, your dipole may resemble a Y.

I have about 40 feet of garden to erect an antenna....Could anyone tell
me if I took 2 20 feet length of twin ladder and shorted the ends
fed one side of the dipole with twin ladder and connected a 52 ohm
resistor across the other side so the tx would see a match would be
better than feeding a 40 foot endfed through an atu...
My thinking is that most of the small antenna on the market are just
dummy loads with a small amount of wire attached and appear to work so
would my 40 feet work better.. ??

> that indicates this is true?

The forward current hits an open-circuit. The net current is zero.
Therefore, the reflected current must be equal in magnitude and
opposite in phase to the forward current at the open-circuit.
Since the net current goes to zero, i.e. the magnetic field goes
to zero, all the energy existing at that point must
migrate into the electric field thus increasing the voltage. And
indeed, the voltage doubles at an open-circuit indicating that
the reflected voltage is equal in magnitude and phase to the
forward voltage. A simple RF voltage measurement at the open-
circuit will prove that the above is true.

> happening above (voltage) and here (voltage and current)? Inquiring
> minds want to know.

It's (surprise) the reverse of an open-circuit. The net voltage goes
to zero at the short indicating that the electric field is zero at
that point. Therefore, all the energy existing at that point migrates
into the magnetic field. The reflected voltage is therefore equal in
magnitude and 180 degrees out of phase with the forward voltage. And,
indeed, the current at the short is double the magnitude of the forward
current indicating that the forward current and reflected current are
equal in magnitude and phase at a short circuit. RF voltage and current
measurements prove it to be true.

For all-HF-band operation with relatively high SWRs, the
spacing doesn't much matter. 2"-6" is a practical range.
Spacer spacing depends upon wind conditions. Two foot
spacing seems reasonable at my QTH. Some spacers pinch
the insulation on the feedline and thus stay in place.
Very small tie wraps could also be used.

Really Cecil, you shouldn't ask awkward questions like that.

You might gain the reputation of being a wicked troller.

On the other hand, it cannot be denied, your question is apt and could
be considered to be educational. Please continue!

Due to a certain person who ought to know better, I suffer from the
same misinterpretation of motives myself. <smiley>

Reg.

==========

9dB is only one and a half S-units. (Ignoring Roy's ancient S-meter).

The Outbacker may still be well worth the money!

But that's just the Capitalist System which places Religion above
scientific facts. Sorry for becoming a little off topic.

A drop of South African Western Cape helps to keep things in
proportion.

I'm a bit confused by your description. Is this a folded dipole, 40 feet long, with an added resistor in the conductor which would normally be unbroken, inserted directly opposite the feedpoint? Or is it something else? Why not just a 40-foot-long center-fed doublet, with a tuner at the transmitter end? What bands do you want to use your antenna on? What do you want to accomplish with it? (DX, local, intermediate range, ...)

Cheers,
Tom

Hi Friends,

I have two dish antennas at the roof of my apartment.They are lying abandoned
for many years.I want to make use of them.Can i receive any signals through them ? & If possible how to connect my computer to the dish receiver & monitor those signals?I dont have any idea about how to get started.Can any one give me a nice suggestion on how to utilize them ?& whether any interesting activity can be carried out ? I require a step by step complete instruction to carry out all the required activities.Please guide me !!!

The feed goes to the centre..The ends are strapped together and the resistor
connects between the free ends opposite the feed connection...

I'm afraid we need a schematic. Is this correct?

```
20ft 20ft
+-------------------FP------------------+
| 52 ohm resistor
+-------------------FP------------------+
```

Two foot spacing between spacers, not between wires.
I tried 4 foot spacing at first and it twisted in
the wind so I installed twice as many spacers.

9 dB is also the gain of a good long-boom 4 element Yagi over a dipole.
You'd have to drink more than a spot of the wine to not see the difference.

If the center of the dipole is NOT supported, I've found the worst problem
is the ladderline breaking -- from flexing caused by wind, etc. -- just
below where it is connected to the antenna. My current dipole has a center
support, but I've read that making the last section(s) of ladder-line out
of stranded wire will reduce the flex-breaking problem.

Paladin:
I have been using the Cobra ultra-lite antenna since
the fall season. I had to cut
the feedline to 80ft. of 450 ladderline,and then add a good 4/1 balun
at the window,and then
i had to add 50ft. of good grade coax to my T-network tuner.
I can tune all of 160 with no problems. I also can use
the amp, about 4-500watts
output WITH no sparks or rf on equiptment. I'm on the 2nd floor
here. There were some
"growing" pains at first,but no it's doing fine. It gets out rather
well,with or without the amp.
I'm still a bit confused though. I still seem to NEED that
feedline LENTH. TOTAL.....
80ft. of L.L. the balun,and then 50ft. of coax. That's 140ft.
total. Works great,though !

73's, Paladin

I've had one on my Ford Ranger for several years with a 10M hamstick. It worked just fine. It was fairly easy to install...I had to remove the taillight assy to get access to the bottom of the pocket but that was not a big deal. I also had to drill a hole in the bottom of the pocket and needed a drill extension to reach but that wasn't too big a deal either. Altho the hamstick probably didn't tax it much, it seems to be a pretty rugged unit and seems to me to be a great idea. It's held up fine for quite a while (can't remember when I bought it) but I just removed it a few weeks ago when I gave the truck to my kid. It got a little rusty on top where the hamstick screws in but the rest of it is aluminum so won't rust. I'd certainly recommend it based on my experience with it. If the one I have will fit your truck, I'd make you a deal on it...

Well Amos, I misunderstood the two foot spacing to be wire spacing
rather than spacer spacing. Both spacings are discussed in the space
of one paragraph, and it is a little open to misinterpretation. I
thought he may have meant wire spacing and two inches rather than
feet... hence the reference to the measurement system. Cecil did clear
it up.

BTW, two foot is closer to 60cm (60.96cm).

Owen

Source record: 65598

Have had two mounted in an F-250 Super Duty. Had them mounted in an F-250 light duty before that. Have been using a pair of hamsticks on them up until last year. Last year I put a High Sierra SideKick on the left side of the pickup and used an 80 meter hamstick on the right. Can't get the SideKick to tune on 80 meters, it is supposed to but have not had any luck with it yet. Still playing with making that work.

The mounts fit as advertised and heavy enough to handle just about anything you want to mount on them. Easy to install with standard hand tools for the most part. One reply said they needed a drill bit extension, true if you drill from the top. If you come up through from the bottom you won't need an extension.

I did make a special tool to make things a bit easier however. Instead of using a open end wrench to tighten the bolt from the bottom I took a box end wrench, cut it in half so it fit better while tightening and then cut a slot in it for the coax to pass through. Just seemed to work better and I keep it in the pick up in case I need to tighten the bolt or do work on the mount.

Have been real happy with mine.

Roy, you have the unfortunate habit of changing the subject in the middle of a discussion in the forlorn hope of it not being noticed.

What have 4-element yagis to do with Outbackers?

By switching to Chinese "Great Wall" white wine I can make my S-meter read whatever I fancy. You ought to try some!

But perhaps you are a teetotaller who has never had the pleasure. If in fact you are indeed a teetotaller, then, I must admit, you deserve congratulations for having evaded the 'demon' drink.

It's all in the genes, anyway! I acquired it from my Grandmother.

Thanks to all who answered -- I really appreciate your comments.

Mark:

Your experience is especially relevant as I have just purchased a used Mazda
B4000 -- basically a Ranger with a Mazda nameplate. I lost my 16-year-old
Nissan pickup along with an FT-857D in Hurricane Katrina (go to
www.schlatter.org to see some ugly photos) and am replacing it with the
Mazda. I rescued the ASAT-120 from the hurricane and bought a new FT-857
last week; I plan to install two antennas on the truck, dual-bander for 2
and 450 and the ATAS-120, will put them in the rear stake holes.

Thanks again.

73,
Joe

241. Matching network for end-fed half wave, Q calculations etc.?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-06 03:10:45 UTC
From: kiddi@marel.is
Message-ID: <1136517045.065705.123740@g44g2000cwa.googlegroups.com>
Source record: 65608

Hello:

I am contemplating a half-wave wire antenna for the 160m band and would end-feed it against my roof as a counterpoise. If the wire length is carefully trimmed I should get a high feedpoint resistance with negligible reactance. Then comes the question of how to match this to a 50 Ohm system.

The standard approach is using a parallel LC circuit and either make a tap or a link for the 50 Ohm connection. In this case, how should I select the L and C, as there are multiple choices leading to the same resonance frequency but with different Q values. Any suggestions?

Or, would another matching network be more desirable, for example in terms of loss? An L-network might do the job, but it is not immediately clear to me if it would have any advantages or disadvantages over the parallel circuit. Any comments?

I will be running substantial power into the antenna, so it is important that the solution does not result in excessive losses (heat) or voltages (although this will probably be inevitable at the feedpoint).

> differential current?

There's the rub, you see. It's RF and, on some frequencies, standing waves
don't NEED to feed current to a ground for there to be common mode currents
on the line. But yes, whatever current is required at the end of the
transmission line will seek to ground itself through the radio.

My amp had the output coil center-tapped to RF ground and the feedlines
were tapped off it an equal amount on either side.

No, I mean ELECTRICALLY balanced. And with the feedline at right angles to the antenna so that it doesn't pick up anything by induction. It's a tricky thing to do, yet back in the old days hams used to feed dipoles or extended double zepp antennas with open wire line and not get much RF in the shack. I know mine didn't. I was putting nearly 700 watts into the antenna and you could touch the amp chassis without any RF burns. Didn't have the fancy tools I have now for testing things, but still managed a good, clean and loud CW signal from an angled dipole. Worked a lot of DX on 75 with that antenna, including a nightly sked with Midway Is. for traffic (from Vancouver, BC.).

If you're looking for transmit efficiency, then a resistor is not going to help you except to keep the standing waves down. You don't, in practice want such a resistor to be dissipating more than about half your power. Even that much is a three decibel loss (about half an S unit).

If it was my space, I'd start as high as I could get at one end and run a sloping dipole with 300-ohm or 450-ohm feeder to the atu. Make sure your atu has a 4:1 balun in it or get a balun that can give you at least this ratio. And just feed the nice sloper on as many bands as you can tune it! It won't be earth-shaking on 80m and will probably wimp out on 160, but I bet it would be tolerably good on 40 and really decent on 30 and up.

Dress the feedline away from the main wire at right angles and twist it a bit. Make sure to follow proper line-dressing procedures where you bring it into the house (or use a 4-1 balun and run coax the last bit). And fiddle with the length of the lower arm of the dipole until you get no common-mode antenna currents on the feeder, say on 30m. That should do it.

I now have use of a b-directional coupler for HF and would like to perform the following 'tests' however I do not understand them. Can you explain the last a different way. I don't understand "two 50 Ohm loads in parallel with the stub".

Tests of stubs are now clearly reading correct for various lengths across frequencies. That is once the 1/4 wave is determined the next odd and even is very predicable.

Thanks,
Dan

Parallel two 50 ohm loads with a tee piece, then use another tee to
put the stub in parallel. The tees will be imperfect, but at HF, the
impact should not be major.

>
>Tests of stubs are now clearly reading correct for various lengths across
>frequencies. That is once the 1/4 wave is determined the next odd and even
>is very predicable.

Do you get the correct answers for 1/8, 3/8 wave stubs in parallel
with a 50 ohm load? (1/8 wave s/c stub has an impedance close to
0+jRo, and you need to put it in parallel with the dummy load, so
series equivalent is 25+j25. 25 ohms in parallel with 1.8 wave s/c
stub should be around 20+j10. Put a 25 ohm load at the end of a metre
of coax and check its transformation at different frequencies
(equivalent to quarter wave, eight wave etc) against your Smith Chart
prog.

They are some examples, work some out for what you have at hand.

Prove that your measurement system works on predictable loads.

Hi - just wonder if anyone has any comments on the MFJ 974H tuner, please. I am thinking of getting one to use with a 260' centre fed antenna and balanced line. It seems the ideal tuner to use having a direct balanced output and not one via a balun.

Many thanks,

Peter

GM Kris

I use an end fed, inverted L half wave on 160 meters on 160, 80 and 40 meters where it has a feed impedance of about 2600, 1600 and 700 Ohms respectively. This allows a remote tuned L network to be used for a match to 50 Ohms on all 3 bands without need for switching the capacitor from end to end of the inductor. My inductor is a piece of 2-1/2 inch miniductor, tap switched with a motor driven switch, and a motor driven vac variable. It allows a below 1.3:1 match across the entire band on all 3 bands and has been a very effective HF antenna for some 15 years. The bottom of the antenna ties to a control box thru a fairly small ceramic feedthru, (maybe 2 inches long) and Voltage has never been a problem even with 1500 Watts out. Fed against a 90 foot well casing that just happens to be in the right place, and a counterpoise under the flat top.

When you don't KNOW that your ground is zero Ohms, feed as little current into it as possible!

Regards
W4ZCB

> total. Works great,though !

When the length of 50 ohm coax to the 50 ohm source
has a large effect, that is usually not good news.
We are usually aiming for a low SWR on that section
of feedline and if we are successful, length doesn't
much matter. Here's what can be happening:

The impedance looking into the ladder-line with an
SWR of 18:1 is 25 ohms because that point is a current
maximum point. The 4:1 balun takes that impedance
down to 6.25 ohms, a lossy condition for the tuner and
an impedance it may not be able to match. 0.15 WL of 50
ohm coax (SWR = 50/6.25 = 8:1) will transform that 6.25
ohms up to 17+j65 ohms, an impedance the tuner can handle.
Have you measured the SWR on the coax on the antenna
side of the tuner?

If one doesn't know what impedance is being seen by the
balun, a 4:1 balun may not be the best choice. It may
even be a bad choice.

An parallel LC network like you describe is usually made with L and C having reactances of roughly 200 ohms or so. That generally gives a loaded Q that results in good efficiency. As you suspect, the voltage will be high at the end of the antenna no matter how you feed it.

Wayne,

Welcome to the wide-world of the inquisitive.

*** Please understand, I'm not trying to be, snooty, a wise-guy or know
it-all. I'll say that I think you are trying to use an intuitive view when
you don't have the proper background/experience to base the intuition on. I
think that you are trying to use "standard" concepts when trying to
understand waves. Intuition comes from some kind of experience that tells
us how things work, but, in regular life, we only gain experience from
mostly "normal" things. Waves are a bit different and it takes some new
experiences to gain that intuition. That's why they teach those wave tanks
in high school -- it give us some understanding of this wave phenomenon.

I can liken it to trying to understand multiplication when all you know is addition and subtraction. Moving to multiplication or division isn't really hard, it just takes some new concepts we hadn't seen before,. However, once we understand it, it's "simple" and the concepts become second nature. We need to realize that some NEW concepts are needed to understand waves, in general.

On to waves... Someone may be able to use pure math and "explain" waves, but there are more intuitive (gut feel) ways which help. Besides, I'd have to work really hard trying to reconstruct all that math from college. (I couldn't solve a triple integral now to save my life)

Waves can be hard to explain in terms of ONLY current and voltage - when we try to use our purely physical experience. I work hard to form mental models of how electronics works and found that there are some areas that are hard to understand with a simple Newtonian understanding (though I do my best to keep my "mental models", as I call my understanding, as simple as possible) - and it has served me well when trying to understand this stuff and explain it to others.

The best analogy for waves is waves on water. Thought there is a major shortcoming in that electromagnetic waves in space don't need a medium to carry them, the rest works out pretty well. On a transmission line there are waves and they behave like water waves.

Some important concepts to possibly help.

Water has mass and it takes a force to move it.

When a force (a rock or wind) pushes on the water, it moves in a certain way - very analogous to electrical current.

In short, a body of water has something analogous to a characteristic impedance. "Push" it with a voltage and it responds with an amount of current according to the analogous "ohm's law" of water.

When the water in one place moves, it pushes on the next bit of water. That push causes a motion in a manner in a way only water can respond (with its "ohm's law"). This is what makes waves happen. There *IS* "something" moving along with that wave. Now put a wall in the water - the edge of the tank. The wave reflects--we CAN SEE it with our own eyes. While you can do some force, mass, acceleration and velocity math and make it all work out, I'll stop here.

Going more general on you here... Some time go I realized that thinking about water pushing on water leads to something like a "characteristic impedance" of water. This concept allows the idea of the motion of the water being transferred to adjacent bits of water and this leads to a wave "propagating" / traveling` over the water.

Now, with this in mind, whenever the stuff that is pushed on by the water does not respond just like water, something different happens. Since the two extremes are a short and open, it is reasonable to assume (and correct in a very general cense) that whatever does happen is somewhere between the

"open" and "short" behavior.

Unfortunately, with water, it is hard to come up with both a short and an open, so this model falls apart a bit. However, the Slinky toy, stretched out on the floor can be observed and have either a short or open placed at the end---as well as other various "loads".

For the "short" hook it to a solid, stationary object (a wall). For the open, put a long string between the far (load) end and the wall. For the others, you can put dashpots and other springs (of different size and therefore "characteristic" impedance).

I know this is a digression off your question, but I think you should study waves in other media which are more directly observable to feel better about transmission line waves.

Hence your following comment and Lew's explanation is how we look at it. There is a summing of things going on at the "load".
> >
> >> In this case, there doesn't seem to be any non-math or intuitive feel
> >> for why the short should cause this--either for voltage or current.

> > magnitude and out of phase.

*** Switching to voltage here, we realize that there is no such constraint on the voltage to be zero at the open, but what can it be? It's probably SOMETHING.. If we believe in waves and reflections, one possibility is that it is in phase, therefore the sum is double, but alas, I can't muster, at this time, an explanation of why in-phase. Perhaps someone has a better "mental model" that I.

> > Likewise, when the line is shorted, the
> > voltage is zero, and the only way that can happen is for the reverse
> > voltage wave to be equal in magnitude and opposite in phase to the
> > forward voltage wave.

*** Switching to current at the short, leads to my reasoning just like the above and the same lack of an "Intuitive" explanation.

Lew uses the characteristic impedance view below and that works for me, but then, I think I understand all this already! I think that if you 'believe', so to speak, in the Characteristic Impedance concept, this makes more "intuitive" sense. Good luck. Remainder un-edited for continuity.

256. Need some pointers on building UHF/microwave 50 ohm termination/power splitter

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-06 21:58:52 UTC
From: Paul Burridge <pb@shove.your.spam.up.your.arse.atlanticstar.co.uk>
Message-ID: <oeatr1hrg39mb6ra4963tuqesncht6qrh7@4ax.com>

Hi all,

I need a couple of accessories to enable me to make some phase
measurements with my HP network analyzer. I'd thought I could pick
these up on ebay easily enough, but note the lack of availably with
surprise and dismay.
I need to therefore contrive two precision parts:

Firstly, 50 ohm load that's essentially non-reactive up to 1.3Ghz.
Power handling only need be a few tens of miliwatts. N-type
connection.

Secondly, a 50 ohm power splitter (one feed-in; three outputs) N-type
connections, again flat up to 1.3Ghz. No switching needed, thankfully.

If I can't source these parts elsewhere, how feasible is it to make
them up and can anyone point me to any designs on the web that might
fit the bill?

I'm aware that the introduction of any stray reactances into the
devices will render all subsequent measurements invalid so I need to
get these parts right. At least 1.3Ghz capability should be achievable
for a hobbyist with care.

Thanks,
P.

Hi Paul,

Take a look at Mini-circuits (www.mini-circuits.com). They seem to stock
what you are after.

You can make a pretty good 50 Ohm termination with a PCB-mounting SMA connector. Cut off the centre pin of the PCB-end of the connector leaving 0.5mm or less protruding (careful of your eyes, the pin can go shooting off pretty fast, it's hard metal), and then solder two 0.1% 100 Ohm 0603 resistors between the centre pin and the outer (ground) part of the connector. The resistors should be diametrically opposite.

I made one with 1% resistors and got the following:
s11 < -30dB up to 6GHx and
s11 < -47dB up to 500MHz

It helps to tweak how flat you lie the resistors on the teflon at the back of the connector, but without a working VNA you just have to accept what you get.

If you want a termination with a N connector, then you could use a really good adapter with the SMA termination I mentioned above, or work out something similar with a N connector however I have never tried that since I mostly use SMA anyway.

I think a very accurate / flat power divider would be fairly hard to make well unless you can get boards made with microwave substrates. If you can work out your measurement setup such that the flatness etc of the divider is not so important, then that would help.

There's a guy in the UK selling a one input two output type power divider with N connectors and a 50 Ohm N termination on e-bay at the moment if that helps you.

Chris

How about using clamp N-types *and* soldering them?? You'd have to
drill a hole or two in the outer casing for the solder, but wouldn't
it be the most secure solution?

Two SMD 100R resistors in parallel is good; six 300R resistors spread symmetrically around the centre pin would be better (if you can fit them in).

You can buy 50R terminating resistors on a circular alumina substrate with a hole in the middle, where the conducting pat runs from the (metalised) rim of the inner hole to the (metalised) circumference. Finding them isn't easy, but they do offer the theoretical minimum of inductance.

You should be able make a pretty accurate and flat power divider in a metal box between two bulk-head-mounted coax sockets by stringing together 0603 or 0805 0.1% SMD resistors with bits of 22swg wire in a neat and symmetrical birds nest. A fiddly job, and you'd probably want to use continuous solder seams to seal the box when you were finished to avoid creating a slot antena or two.

The 0.1% SMD resistors are available off the shelf from Farnell - IIRR you have buy them in multiples of five, but they aren't that expensive and if want to built a low-inductance symmetrical structure you need to put three or four resistors in parallel (six would be nicer, but you'd need to be a Jim Williams level artist with the soldering iron to keep it neat).

A two-output splitter,IIRC,uses 3 25 ohm resistors in a Y config.
Use a double-sided PCB for the ground plane between the three N connectors.

In older handbooks, they often say that the parallel LC circuit used to feed the end fed wire should replicate the output tank circuit of the transmitter.

I have an end fed inverted "L" for 40 meters that works really well. It's 32 feet vertical and 98 feet horizontal, with the far end 8 ft. off the ground.

I use a parallel tuned circuit at the base in a weatherproof box and it's fed with a 100 feet or so of RG 8 buried in PVC. The coax center conductor is tapped up a turn or two from the bottom of the coil.

I consider this a single band antenna, and I use it only for 40 meters.

> I am making the mistake or explain it to me the correct way to
> calculate Tau(d).

Different texts use different subscripts. Is Z(r) the load
impedance and Z_not the characteristic impedance? What is 'd'?
Are you using a Z-parameter analysis?

From "Fields and Waves in Communication Electronics", by Ramo,
Whinnery, and Van Duzer, page 28:

rho = (ZL-Z0)/(ZL+Z0) = Vref/Vfor

tau = 2*ZL/(ZL+Z0) = (Vfor+Vref)/Vfor

where rho is the voltage reflection coefficient and tau is the
voltage transmission coefficient. ZL is the load impedance and
Z0 is the characteristic impedance of the transmission line.

> direct balanced output and not one via a balun.

There was some discussion about moving the balun from the output
of an unbalanced tuner to the input. It is generally accepted
that action will not improve things very much. The only difference
in that action and what MFJ has done is that, in the MFJ-974H,
there is some series capacitor impedance opposing the common mode
current. That series impedance varies with capacitor settings and
is therefore not constant.

The Johnson Matchboxes suppressed common mode current through link
coupling (no balun required). The MFJ-974H doesn't use link coupling
so the common mode current flows right through the tuning caps. And
the MFJ-974H does indeed have a balun function on the source side of
the network. It appears to be a w2du 1:1 choke balun. So the MFJ-974H
is not as good at choking common mode currents as the Johnson Matchbox
and not extremely superior to an unbalanced tuner with a w2du 1:1
choke balun on the output.

I'm not trying to discourage anyone but the MFJ-974H may not be an
extreme improvement over an unbalanced tuner with a w2du 1:1 choke-
balun on the output.

Hi,

I received this message from a colleague but I cannot answer him. I d
not know these systems.
Could you help me ?

My company has installed a Radar Tower for Port survaillence. The tower
is about 50 meter height on top of the of a 3 stories building roof and
my office building just below the tower on the same level, 20 meter away
from the tower. At the same time, the surrounding is my working area (
Jetty Terminal for ships loading and unloading activities). I can say
that I'll be around that area 12 hours a day for another 20 years.

My question:

Is it safe to work in that area????

Thanks in advance
Thierry

>
>I must ask, what is the purpose of this?

The (thumping great) service manual that came with this VNA gives
various levels of tests that can be performed oneself prior sending
the thing away for calibration. The power splitter together with a few
other basic items enables the analyzer to 'check itself' for
fundamental operating fitness.
I'm eager to get measurin' stuff, but need to establish some basic,
satisfactory level of accuracy first. Being just a hobbyist, I don't
require any absolute standard, thankfully!!

Hi Thierry

I dont have the answers on hand. There are however exposure limits set by legislation in various countries. You will often find websites that help you determining what the conditions are at your location. Amateur radio stations for example meed to be concerned about EMR levels when the radiated power gets high.

If you cant find anything on your countries radiocomm authorities site have a look at the US's FCC or Australia's ACMA sites. The exposure limits tend to be a fairly universal thing. I would suggest too that to license such a radar structure a EMR study would have to be done as a matter of course. This is a important part of spectrum and safety planning that is certainly the norm in Australia.

I would suspect too that being used for ships at short range the output power would not be nowhere near what is used at longer distances. If perchance it is used for longer range as well, then the antenna system would be designed in such a way that most of the radiated power is horizontal and as such only a small component would be aimed down at your office/work location. This is the same logic as placing a cellphone antenna up very high so that nearby EMR is not an issue.

My gut feel is that it is safe. You havent of course provided power and antenna pattern figures for the installation.

Cheers Bob W5/VK2YQA

I have spent most of my working life around various RADARs starting in my late teens at the Royal Radar Research Establishment; which was flooded with RF from numerous operating systems on a large variety of frequencies - throughout much of the establishment a neon bulb would often light just from the RF environment.

The last 25years or so before retirement were in a building with numerous installations, including a long range L band ATC primary and secondary installation which provided some entertainment in idle hours as I computed the radiation pattern - with a surprising degree of accuracy - from the noise emanating from my office radio as the beam swept by.

Across the hall was a lunchroom with a large health and safety warning sign on the door that a microwave oven was in the room. Looking out the window one was staring down the throat of an operating marine RADAR less than 30 feet away!!

To the best of my knowledge no one who worked there has developed any strange illness that even rumour has related to the RADARs. I retired 10 years ago and have no significant illness.

Oh yes, and my kids seem to be relatively normal. (Maybe because I wore aluminum underwear?)

Dave

Hello Jawod,

I have buit a twin leed for my center feeder dipole with PCV tubes:
http://www.barbaxoops.com/modules/xcgal/displayimage.php?pid=57&album=7&pos=2

Tubes are after filled with glue. You can see here the final result (click
on the picture to enlarge it):
http://www.barbaxoops.com/modules/xcgal/displayimage.php?pid=5&album=7&pos=4

Spacing is 5 cm
Distance between spacers is 60 cm

It has been installed for 3 years. It has resisted to many strong winds.

Good luck

MATCHING END-FED 1/2-WAVE ANTENNAS TO THE TRANSMITTER.

Instead of depending on hearsay and old-wives tales, there is a logical way of selecting tuned-circuit L and C values.

To begin, in the case of impedance matching it is always required to maximise power efficiency.

It is the power lost in the tuned circuit which matters.

To minimise power lost in the tuned circuit it is necessary to minimise the current circulating in it. (Circulating current is the antenna current times working Q but there's no need to know what Q actually is.)

For a given radiated power the voltage across the tuned circuit and antenna when at resonance is fixed. So to minimise circulating current the reactances of L and C should be as high as practicably possible. That's obvious!

So for a high reactance of C (which is approximately the reactance of L), C should be mimised.

The limit on the smallness of C is the minimum setting value of the tuning capacitor, plus coil self-capacitance, plus stray capacitance associated with wiring and connections to the end of the antenna, plus an allowance for the antenna not being exactly at resonance, plus a small 'safety' margin to allow the tuning capacitor to be adjusted to either above or below resonance.

For half-wave antennas at frequencies below 11 MHz a tuning capacitor setting of 20 or 25 pF is suitable. This choice automatically sets the value of the inductance (which is usually higher than the inductance value of a roller inductor and can be home-brewed quite easily.)

The maximum setting of the tuning capacitor allows the circuit with the antenna to be tuned to the lower frequency bands. But efficiency will be reduced on lower frequency bands due to smaller reactances of L and C and the greater circulating current. Note that the reactances of L and C are always approximately equal to each other.

Theoretically, if the antenna length is slightly shorter than 1/2-wavelength, then it is impossible to obtain an impedance match with this particular circuit. You can't have a tuning capacitor less than zero pF. It is prudent to select the overall antenna length to be a few feet longer than 1/2-wavelength at the desired operating

frequency.

On the other hand, it is just as well to remember, a non-resonant end-fed antenna wire is no less efficient than an exactly resonant wire provided it can be matched to whatever load resistance is required by the transmitter. (And the load resistance presented to the tansmitter as indicated by a TLI has nothing to do with the so-called, and imaginary, SWR).

As Walter Maxwell has peviously pointed out, SWR = Short Wave Radio.

But, despite its diagramatic simplicity, a parallel tuned circuit is a not-so-simple, quite complicated arrangement when used as an impedance matching transformer between an end-fed antenna and the transmitter. No maths needed - just arithmetic.

Slight change of topic -

I am presently imbibing White, Argentinian, Chardonnay Torrentes. I do hope my use of plain English language does not lead to misunderstandings.

May I add that I much prefer a decent, intoxicated, political opposition-party leader to a sober, war-mongering Tony Blair. At least a few of you USA citizens must be acquainted with the relatively trivial events taking place in the 'mother' country. In sympathy with what's happening in the US.

When will you impeach your so-called president and rid yourselves of your secret Nazi/OGPU CIA police. I'm sure the Constitution does not allow such people to exist.

We would be happy to confine both Blair and Bush, here, in the historic Tower of London, chained to the cold stone walls, for an indefinite period, on bread and water, without access to legal representation, as so many other kidnapped prisoners (disappeared people), for years, are being presently detained without sound reason or charge.

Have you no conscience? Or have you no idea what a map of the World looks like?

To obtain an elementary understanding of a simple tuned circuit as an impedance-matching circuit, download program TUNEHALF from website below. There are other programs available related to the same subject.

Intoxicated BS Diatribe snipped

Or, use an "L" network. Same number of components, and it will even match impedances that call for negative component values in a parallel tuned circuit.

=====================================

Actually, with an exact 1/2-wave antenna, an L-network suffers from
the same disability as does the simple L and C tuned circuit.

This is why automatic antenna tuner manufacturers, which use
L-networks, state in their operating handbooks that exactly 1/2-wave
antennas should be avoided.

But it is not an important matter. Very few antennas are EXACTLY
1/2-wavelength in length. And it is a simple matter to shift the
resonant frequency up or down a few KHz.

Reg, G4FGQ.

rf 'ground' is a real misunderstood thing. and things like this point out just how poorly understood it is. there is really no need for a radio to be 'grounded' to prevent rf burns or to have an antenna work properly... the important thing is to remember that at that point where the rf leaves the radio on the center conductor of the coax connector the current there must be exactly balanced by a current going the opposite direction the inside of the shield of the coax connector. looking at the worst possible case, just stick a random wire in the coax connector and run the rig off a battery with a short cable and no other 'ground' wire. current flows out the center conductor of the connector into the exposed wire and somehow has to get back to the inside of the connector shell to balance it out... well, the only place for that current to come from is coupling from the antenna wire back onto the case of the radio and from there it flows back into the connector. now, put your hand on a metal part of the radio, or your lip if you are unlucky, and what happens?? you are much bigger than the case of the radio and you are fairly conductive, so now you provide a bigger collector for the current from the antenna so lots of it flows through you to get back to the radio connector... hence rf burns. how to stop it?? provide a lower impedance path for the rf to get back to the connector than through you. that can be a counterpoise wire, a 'ground' wire that collects current from the soil under the antenna, connect the case of the radio to your car and the car becomes the collector... OR add an equal sized second wire that 'balances' the current from the wire in the center conductor... the critical point is that it mut be very nearly identical to the first one so the current in it is the same... a dipole that is symetric with respect to the feed point will work, but you have to watch out because the case of the radio is connected to the coax connector also, which tends to unbalance the equation since there is no equivalent lump of metal on the center conductor part of the antenna. to make this job of balancing the currents easier we normally add a length of coax (to get the antenna farther away from the radio) then add a balun to help force the currents in the two halves of the dipoles to be equal so there is no need for current to flow from the radio back into the inside of the shield. a choke on the outside of the feedline also can help, but the reason is different... a choke on the coax creates a very high impedance so that current has a hard time flowing from the case of the radio or outside of the coax back to the inside of the coax. enough rambling, just remember, rf ground is a myth, all you need to do is get those currents equal while preventing the path where they flow from being through you or something else that could be damaged by them.

Dang Charles, I did exactly the same thing in 1957. If you had
asked me, I would have told you to watch out for those metal
microphones when using a Windom.

If the radar antenna is 50m above your friend's level he'll be well
below the main beam.

While radars do typically have very high peak power outputs they only
transmit for a very brief fraction of time then shut off while they
listen for the echoes coming back from the
ships/planes/trains/automobiles/some clod walking his dog/what have
you. This drops the effective power output to a low level. As the
only demonstrated effect of radio waves is thermal (that is to say
they'll heat you up). the end effect isn't much diferent than what
you'd get from somebody shining a flash light at you from some
distance away. If your friend is worried about cancer lots of people
have tried to prove radio waves can do this but it hasn't been
reproducibly shown yet. If there is a link I'd think the research
would have conclusivly proven it by now. Have a look here-

http://www.mcw.edu/gcrc/cop/cell-phone-health-FAQ/toc.html#23B

This is really aimed at cellphone installations but the same general
ideas apply.

It's probably a lumped element Wilkinson power divider design and they work at a
specific frequency range the optimum Z match is where the 1/4 wavelength is set.

If all you need is a resistive power divider, the frequency limits
should be generous. If you want efficient power dividers (with little
loss in the splitter itself) you use wideband transformers to get the
power split.

> migrating...will small wire "stays" modify feedline characteristics?
>

I've heard some use well-varnished dowels as well as pvc pipe, and pieces of
scrap vinyl siding cut to size and drilled for spacers.
and for stays, I've heard epoxy, super-glue, and hot-melt glue works.

If the pieces of vinyl (siding scraps) were folded into a "V", then drilled
for the wire on each side, the springiness of the vinyl would probably hold
itself in place without glue.

spacing of spacers would depend on the stiffness of the wire. Use common
sense - just need to keep a consistent spacing. It would take more spacers
for flexible, stranded wire than for stiff solid wire. 10 guage solid wire
is stiffer than 20 guage braided stranded wire.

Thanks to all who replied. I checked out the GeoTool website, read their instructions, etc. Then, I investigated my truck and it looks like a simple installation -- the interior of the stake hole is readily accessible with the taillight fixture removed. I ordered two of the GeoTool mounts today -- one for a Radiall/Larsen dual-bander VHF/UHF and one for an ASAT-120.

Will post photos of the installation later.

>I have about 40 feet of garden to erect an antenna....Could anyone tell
me if I took 2 20 feet length of twin ladder and shorted the ends
fed one side of the dipole with twin ladder and connected a 52 ohm
resistor across the other side so the tx would see a match would be
better than feeding a 40 foot endfed through an atu...
My thinking is that most of the small antenna on the market are just
dummy loads with a small amount of wire attached and appear to work so
>would my 40 feet work better.. ?? .....

If you are trying to avoid a dummy load, a resister is the last
thing you want. It should be illegal to add resisters to otherwise
perfectly good antennas.
It's hard to comment about the antenna, as I don't know what
bands, how much height, etc... Not enuff info...

Without knowing which devices you're referring to, I would still guess
that they are based on broadband transformers. "Broadband" does not
mean DC to daylight. And yes, there might be some compensation caps
involved too.

If you want better bandwidth, including DC, and loss is not a concern,
then fully resistive dividers are what you want. An example of a
two-port is here:

http://www.k6mhe.com/n7ws/HP-11549.pdf

These are ferrite transformer hybrid splitters with fractional dB
insertion loss beyond the 3dB split and typically 30dB isolation between
output ports. If you want a DC splitter then they have those too- but
you're not swift enough to see them. They are simply this. What do you
think the loss and isolation is now?:

They did come with the needed switching diodes which were a weak point in
the design and there was later a suggested replacement.

> ----
> Reg, G4FGQ.
==

It was incorrect of me to say that an L-network suffers from the same disability as the parallel L and C tuned circuit. But it does suffer from disabilities of a different sort.

As you say, Harold, the L-network can be tuned to either side of antenna resonance without calling for impossible negative component settings.

The input impedance of a 1/2-wave antenna at resonance is a pure resistance of several thousand ohms. But only very slightly on either side of resonance the series resistive component of Zin falls to a much smaller value - and there arises a series reactive component which can also rise to several thousand ohms. Things change very fast versus frequency.

The automatic tuner manufacturers recommend avoidance of end-fed 1/2-wave antennas because very high values of switched inductance are needed on the lower frequency HF bands to provide an impedance match to 50 ohms. You will be aware, in automatic tuners, that both L and C are switched.

It is uneconomic to provide large microhenry values of switched inductance for use only on antennas which are rarely found, i.e. on end-fed wires which happen to be exactly 1/2-wave resonant.

It is also uneconomic to provide a switched range of small value capac itors, say from 0 to 20 pF.

Whereas, with an L & C parallel tuned circuit the coil is home-brewed, it has high intrinsic Q, it is fixed in value, and tuning is done by varying only the capacitor. Impedance matching to the transmitter is done by tapping the transmission line up and down the coil turns.

It also transpires that the power efficiency of a parallel tuned L & C matching circuit is higher than an L-network which does the same job. That is because the circuit designer has control over choice of L and C values. Whereas, with an L-match, the L and C values are pre-determined by the values of the load and generator impedances over which the circuit designer has no control.

There is an additional complication of L-network design. At certain values of load and generator impedances, the location and values of L's and C's in the circuit can suddenly change versus frequency. And there is always a choice between 2 circuits which perform same job.

Anyone interested can download program L_TUNER from website below.

The antenna input impdances obtained from program TUNEHALF can be inserted in program L_TUNER and the L and C component values compared between one type of tuner and the other.

Remember that with the L-tuner both L and C are variable. With the parallel L and C tuned circuit, in general, only C is variable and impedance matching is accomplished by tapping up the coil. (or by varying the turns on a link-coupling which, by the way, confers other advantages.)

I've got one - defective - I think I popped the switching diodes by accidentally transmitting thru it. I know I've got the dox 'somewhere' - just gotta dig 'em out.

From memory, the four pin cable from the main unit sends a rotating DC bias to each of the switching diodes in the box. There's a diode at the antenna base too, by design. I haven't opened the box yet, but the diode at the antenna base is ITT BA 282 Cathode (bar) to coax shield.

If/when I find the dox, I'll get back to you. Let me know how you progress.

MUCH better Reg.

At one time, my 160 meter half wave was fed with a parallel tuned circuit using a huge roller inductor (5 inch diameter, foot long surplus thing) I used the same motor driven vacuum variable to obtain resonance and the roller "tap" was only to obtain the 50 Ohm match. Was a fine 160 meter antenna, but my 40 meter quad was an eyesore and difficult to maintain, and I had nothing up for 80. Swapping out the inductor for a piece of Airdux and tapping that for 3 values of inductance and selecting those with an old Ledex motor driven rotary switch gave me all 3 bands with an "L" network. Difficult to accomplish with a parallel tuned circuit without appreciable additional complexity, never noticed any difference in performance on 160 meters. We now have two copycat antennas, up for several years. W4GCK and W1TRF, both are as well pleased as I have been. GCK and I have a directional antenna for the higher bands, TRF uses his on all bands.

Regards
W4ZCB

Maybe they are PIN diodes that turn on (conduct) when forward biased?

They sure seem to be :
http://members.aol.com/homingin/DSEfix.html
The ones in the box switch one of the antennas at a time to the RDF, and
the ones at the base of the antennas groung the out-of-use antennas.

I only made that mistake once! That burn was very slow to heal, by the way.
I clearly understood several principles after that. Close-talking the mic
and over-modulation was the least of them.

312. J-Pole Installation Questions

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-09 00:34:45 UTC
From: Paul Proefrock <proefrock@heartlandREMOVEgroup.com>
Message-ID: <Fciwf.52945$7h7.40143@newssvr21.news.prodigy.com>
Source record: 65571

Can anyone help a newbie installing a J-Pole antenna.

Antenna: Copper Pipe Dual Band 2M/70CM. Bottom of long leg is tee. lower leg of tee goes 14" w/ 1/2" copper then transitions to 1" x 36". This is clamped to two tv mast mounts, anchored to a wooden chimney chase.

When I built the antenna, it displayed a relatively flat SWR across both bands, using an MFJ-269. Antenna was free standing in yard, away from anything to affect it.

After mounting, the SWR seems to vary from as measured (1:1.2) to off the map. Thought it was maybe bad coax (LMR-400) but as I checked it, the SWR came back into line. Someone told me to ground the lower end of the j-pole, as if it were clamped to a tower. I did this and the SWR goes off the map.

Should a J-pole be grounded? if not, how do you protect it or the structure from a lightning strike?

Thanks

Paul P

A j-pole should be insulated from a conductive mast and a choke type
balun use on the transmission lines. Not so much for matching but to
keep the maximum signal towards the horizon and not shoot up at high
angles. Unless you want to talk to airplanes.

This is where those artificial ground things come in handy. But the end of
the counterpoise needs to be where it can do no harm, as that's where the
artificial ground sticks the voltage.

The G5RV antenna can be found by googling. Anyone using this arrangement. It uses a coax feed to balanced feed (which variously acts as radiating elements, depending on the band). The author says a balun is not needed but then describes an RF choke that sounds a lot like a balun. I am also concerned about TVI with this system.

I'm not crazy about them at all. I'm not a fan
of switching feedline types midroute to the antenna.
This applies to other antennas as well. The G5RV
was designed mainly as a 20 meter antenna. I'm
not sure who decided it was the magical platform
for a multiband antenna, but someone did...
Someone should get a rope I think... :/
You would be much better ditching the coax and
choke, and running straight ladder line, if feeding
all bands with a tuner. I think coax fed antennas
should see a proper match at the feedpoint of
the antenna. If I'm going to use coax, I'm going to
run coax the whole way.
Some run the "carolina" windoms the same way pretty
much.. :(I've directly tested simple coax fed
dipoles against both of these antennas. It was
fairly ugly. The simple dipole thrashed both of them
handily. There is a good bit of loss in all that
feedline clutter. Some bands worse than others.
If you are going to run a tuner and ladder line for
all band use, a simple dipole on the lowest band
to be used is a fairly decent compromise. No need
to add excess feedline clutter. And loss. :(
If you use ladder line all the way, and tune carefully
using the least inductance, you will have a
fairly efficient system on most all the bands.
Most tuners include a 4:1, but some prefer a 1:1
balun instead.

Source record: 65477

The choke balun is used because the G5RV is fed with balanced line. They work well, last a long time and require a tuner. I have never had any TVI with one, nor did I ever expect any.

APRSPoint 2.2 is released. New features include,

1. Added TNC data view and TNC data log,
2. Enabled auto connect for AGW packet engine,
3. Fixed a bug handling weather station data,
4. Ability to load a default map view at startup,
5. Restore TNC settings when program exits.

and many more. The holiday sale is also extended for 2 more days.
Visist http://www.aprspoint.com for details. Thanks.

Source record: 65485

DOUG,
Depending on how you build the 'hazer', you really don't need
rails. The thing will slide up the tubes of the tower just fine,
won't even bump on the bolts (much). Also sort of depends on just
how 'much' antenna is used and how often it goes up/down, since
there is some wear on the tower. 'Normal' use shouldn't be any
problem though.
A friend built one for me. Not aluminum, and aside from building
muscles I didn't particularly want, worked fine.

Almost any full service lumber yard in Oklahoma should carry barn door
hardware. Also, Home Depot and Tractor Supply carry that sort of item.

Maybe the only one? :-) The G5RV, with tuner, is a pretty
good 80m, 40m, 20m, and 12m antenna. If the series section
is varied from 20 feet to 36 feet, it becomes a very good
all-HF-band antenna. With the addition of a parallel 1000pf
capacitor with the series section at 22 feet, on 75m my "G5RV"
has SWR of 1.3:1 and works as well as a 75m 1/2WL dipole.

Maybe he doesn't quite know what to look for.
Many years ago an article was published here how to make this Hazer type device..It looked heavy on the side of his tower.
If anyone wants the article, I could try to find it and make a scan.
Eskay.

Source record: 65492

Hello Paul,

You do not need to ground the J-Pole antenna because it is a half-wave
dipole feeded with a quarter-wave length.
That's why the total antenna lentgh = (1/2 + 1/4) x lambda

I have built several 2m J-Pole antennae (with copper pipes) without any
problems. The last one was clipped to the TV mast (as yours). The only
problem I have experienced was with a dual band (2m/70cm) J-Pole (your
case). It was solved by ajusting some of the dimensions.

If it is your first J-Pole, I suggest you to built first a mono-band (2m).
You will succed because this is the most easier antenna I have ever built!!!
Then you will be able to handle a dual band J-Pole.

Do not vanish!!!.... This is a very nice antenna. It's main benefit is the
very low angle of its radiation over the horizon (between 3 and 4 degrees).
I did a contact with Marocco from my location (IN88HR) with 10 watts!!! OK
!!! It was a sporadic .... ;-)))

Good luck. Contact me if you want more details.

Best regards

Cross-posted to: rec.radio.amateur.antenna,rec.radio.amateur.misc,sci.electronics.design

(Seems like this should be r.r.a.homebrew instead of the antennas group!)

Beware of the difference between a "power divider" and a "power splitter." (The terminology different folk use can be confusing, because there's not good consistency in the useage...) I gather, without reading every word of this thread, that you want to make network measurements, and the splitter is to provide levelling: either a reference channel or actual amplitude control of the exciting signal.

So for a two-way, you want simply an input connector and two output connectors, with a 50 ohm resistor from the input to each output. The trick is that you want as near perfect symmetry between the two channels as you can get. Ideally, each 50 ohm R will be in a coaxial environment where the output end is 50 ohms and the input end is 100 ohms, but you don't have to control that very accurately to get it to work well to 1.3GHz. With that arrangement, the source "sees" 50 ohms if each output is loaded with 50 ohms, and if you use one output channel to control the level, the level stays constant at the input connector (since that's what's being monitored) and that is an EFFECTIVE zero impedance point, much as the inverting input to an op amp is a virtual ground. The the second output port then shows an effective 50 ohms source impedance. You can show that monitoring the reference channel instead of actually using it to control the level is functionally the same for circuits which are not significantly level dependent.

For a three-way, you want 50 ohms to each output port as with the two-way, but now since the three outputs in parallel (each 50 ohms load plus 50 ohms series resistor) result in 33.3 ohms at the junction where they come together, you need 16.7 ohms in series from there to the input port, to provide a 50 ohm load for the source (assuming 50 ohm loads on each output). Note that 16.7=50/3. So you can make that splitter with 6 50 ohm resistors.

Being just resistive devices, the only thing that limits the frequency response is parasitic inductances and capacitances--not being able to make the environment "perfect". But that's only a problem on the high end, not the low end. DC is not a problem for these devices. However, they are much more lossy than a power divider, which ideally has no loss in the divider itself, at least with proper loads.

We had a need for some DC-6GHz splitters. The commercial ones we had were rated to 3GHz, and indeed they weren't all that wonderful much beyond that. A search for commercial ones that were rated to 6GHz came

up empty. So I designed a 6GHz one, using 50 ohm 0805 SMT resistors, with some help from a mechanical engineer. The three output ports are in one plane, radial spokes from the central node where all four resistances come together. The input port is perpendicular to that at the center. The resistors are all soldered together at one point, zero lead length except for their terminations and the tiny ball of solder. To get good performance to 6GHz, there's a screw that adjusts the capacitance from ground to the central node. It's all housed in a hexagonal aluminum block, with SMAs radiating out. I was able to build a prototype that worked acceptably, using only PC mount SMAs soldered together. I'd have a lot of confidence, based on that, that I could make one that would work quite well to 1.3GHz even without much in the way of test equipment to check it.

And you should have no trouble at all making some very decent loads using the techniques others have mentioned. FWIW, I've had better luck using two 100 ohm SMTs radially opposed than using four 200 ohm SMTs with 90 degree spacing. I didn't investigate just why, but assumed it had to do with the parasitics inherent in the parts.

Cheers,
Tom

(I'm a bit surprised you need a three-way splitter. Are you measuring two DUT paths simultaneously??)

Hi John,

The "Center Feeded Dipole" (feeding with twin-leads) would give you better performances and no TVI.

But if you prefer the G5RV do not use any balun (with magnetic stuff). In somme cases, baluns brings losses (if high SWR on the line). You may find many people that will say that their G5RV works perfectly well with a balun .... they are lucky !!!
It is better to connect the coax directly to your antenna tuner.

Good luck

Cecil, get yourself up to date.

A terminated rhombic is only 50 percent (or even less) efficient.

It transmitts to, and receives from, only half of the available directions. A wicked waste of power. I can't imagine why anybody bothers to use one which is not rotateable.

Have you ever erected a 160-meter or 80-meter or even a 40-meter rotateable rhombic? <smiley>

Reg, G4FGQ.

Actually, that is not true.

A big enough rhombic is nearly self-terminating. The energy radiated
is not available to the terminating resistor and thus is not -lost-.

I completed my 2-meter Worked All Continents award by working VK5MC,
who was using stacked rhombics (350 feet/leg), partially steerable by
a rope and pulley arrangement. Worked for me [g].

Thanks to all for advice!

It seems likely that, as I re-enter ham radio, I will be using a rig
with an SO-239 plug as an output. The unit I am considering has an
internal ATU. So, it would appear likely that SOME coax will be used.
I've read articles that indicate a simple PVC pipe wound with 20 or so
turns of coax is sufficient for a coax to dipole configuration.

I guess I am trying to have a multiband dipole antenna that uses the low-loss ladder line as part of the antenna on some bands. This seems consistent with the G5RV.

Any thoughts on other designs to accomplish this? Many articles seem to steer clear of series traps in the dipole. I must have TVI as a high potential concern..

Anyway THANKS!

Jean-Marc: nice antenna system...your twin lead looks like coax...is it?

>Maybe the only one? :-) The G5RV, with tuner, is a pretty
>good 80m, 40m, 20m, and 12m antenna.

Depends what you compare it to... I bet my paralleled
80/40/20 dipoles would beat it on all those bands.
Maybe even 12m. I'm not going to lose too awful much
even though I'm running 213 coax. You may have some
cases on the higher bands where the gain may be
better than the dipoles in some directions, but thats still
not a matter of efficiency.

>If the series section
>is varied from 20 feet to 36 feet, it becomes a very good

>capacitor with the series section at 22 feet, on 75m my "G5RV"
>has SWR of 1.3:1 and works as well as a 75m 1/2WL dipole.

You would be the exception to the rule. And I still really doubt
it's the total equal of a simple coax fed dipole on 80m.
The "usual" G5RV that most people tend to buy and run
is one of the most pathetic 80m antennas I've ever used
in my life. Truly a disgusting POC...:(I had the mispleasure
of being stuck on the G5RV at not one, but two field days
in a row. I'd never experienced working FD on a dummy
load until that time. I lost about 3 mm of tooth due to the
constant grinding of my teeth on those weekends.
After that, I *swore* I would never, ever, be stuck on
one of those things ever again. Never, nada, zilch.
Now, I've heard people that had fairly decent signals
with various perversions of the G5RV, but again, they
seem to modify them to work halfway well, and many
run amps, which also help them look a bit better than
they really are. If people want to run those, be my guest,
but keep them at least 500 yards from me. I'll be using
my usual coax fed dipoles.
This trails off to the "carolina" windoms that many people
run in the same appx manner.
Well, on the first FD after the two G5RV nightmares,
I brought all my own stuff to build dipoles on the spot.
I got to the FD, and the first antenna they suggested I
use was a carolina windom that was up in the air
pretty well. Maybe 50 ft up or more. It was fed with
the usual "clutter" and a tuner. "tuner/coax/choke/antenna.
I can't remember if any ladder line was involved on
that one...

Anyway, the first thing out of my mouth was *NO!!!!!".
I'll build a regular ole dipole, thanks, but no thanks.
Not trying to be rude, but I'd had my fill of dummy loads.
Anyway, I built a 40 meter dipole on the spot, and
threw it up in a different tree. It was actually lower
in height than the windom. I then brought out a coax
switch, and hooked both the windom, and the coax
fed dipole to the rig. Now, at first glance, you
would think the windom was doing all the good.
It was "working", and seemed to be just fine.
But then, I'd switch over to the dipole, and
everything would jump 2 S units on that radio.
All signals, noise floor, the whole shooting match.
The windom owner like to fell over. He had no
idea that he was taking that big a hit vs a simple
dipole. Needless to say, the windom wasn't used
after that test. People can run whatever they want,
but many have delusions that these "compromise"
clutter fed all band antennas are just as good as a
simple dipole. It's rarely the case by what I've seen.
Did you actually compare with a coax fed dipole
using a switch, etc? If not, saying it's equal is
just theory at this point. I'd have to see it to believe
it... :/ Heck, I see the difference from a properly fed
tuner/ladderline/dipole setup vs a coax fed dipole.
The coax fed always wins here by a slight amount.
As far as I'm concerned, a coax fed dipole is as good
as you can get in the real world on those lower bands as
far as system efficiency. In the 95+% bracket I think.
Your tunerless setup may be equal, but that's
not the usual setup for most people. Most use
a tuner also. I use the coax fed dipole as the benchmark
by which all others are measured on 80m. Most all lose,
unless they are a gain antenna like arrays or whatever.
Of course, with the dipoles on 80m, I'm usually talking
NVIS, or medium distances. I'm not a dxer much.
But...I had no problem at all taking to EU this past
winter on that dipole in the couple of times I tried
it down in the dx window. . No amp. I haven't run an amp
in 5 years. First call and solid copy too. I forgot where
they were. I think one on G land. One in Spain, germany,
etc..With just 90-100w from the 706. :) But a big NVIS
signal is really what I shoot for. Can't get much better
than a coax fed dipole or loop. Simple is best I think. :)

Gary,
I'm in the process of finishing a new display for my "Roanoke Doppler".
Do a search on that name and you'll get many hits. For just the antenna,
the Homing In Web site has info on both main types in common use. I'm not
sure what the Dick Smith does, but perhaps Homing-In talks about it.

Homing In is the place to start:
http://members.aol.com/homingin/index.html

It has antenna system (typically 1/4 wave whips for the Ham units)
references:
Down a ways on the main page under Home Built:
http://members.aol.com/homingin/newdopant2.html

This specificlly addresses the Dick Smith unit:
http://members.aol.com/homingin/DSEfix.html

You can always email K0OV.

The standard advise from K0OV is to NOT ground the unused antennas, but to leave them open which is in a non resonant state. This is so they have minimal effect on the active antenna and thus do not act like a parasitic element. I'm not sure why, but he recommends having NO amplitude (pattern) effects in your system.

Don't you mean Z_naught (meaning Z0 a.k.a. Z sub zero)? Z_not sounds like
an active-low digital signal line.

A true radio amateur!

Just get a random, bent wire into the air. A single-wire feed helps a
lot. With a modest ground and a simple tuner you have an efficient,
multi-band, go-anywhere antenna system you can be proud of.

Anybody who boasts about his G5RV has never tried anything else.

Reg.

David,

Be careful of that "Match Efficiency" number read out by the MFJ. I
don't remember what they are showing, but I do remember there was a caution
in their manual about just what it was and that it was a rather crude
indicator. Some over simplified readout.

Reg, during the Vietnam War we used a terminated rhombic from the State of Utah [USA desert area] to SEA [AKA Vietnam]as part of the antenna farm at AGA5HI [USAF MARS Gateway Station] for phone patch traffic. It would outperform the Yagi and the LP antenna.

I was AFF1C TDY at AGA5HI [Hill Air Force Base, Utah]

I don't believe there is a net loss of gain in the preferred direction. If one loses -3 dB in the resistor, does one not waste -3 dB in the non-preferred direction [180 degrees from the desired direction]?

Right.....you should hear the bands open up when you launch a kite
antenna. There's nothing like a few hundred feet of random long wire up
in the air. ;-)
WARNING: No one should ever do such a thing for what should be very
obvious safety reasons.

I'm a big fan of cubical quads, but you need allot of room for them.
I'd take one over a yagi any day. I built a two element quad for 10
meters using bamboo fishing poles for the spreaders. The boom was made
from cedar. It lasted about three years before a flying tree limb took
it out. I also made an 8 element quad for 2 meters using 1/2" poplar
dowel rod spreaders and a wooden boom as well. Man was that thing hard
to tune. Weird things happen after the fifth element is added for some
reason. Might explain why most have only 4 elements. ;-) Seriously,
it really kicked ass but the tornadic storm took it out too. I'll not
be making another with that many elements, too fussy but extremely
narrow beam w/incredible back side rejection.

Don't get too hung up on efficiency. What counts is signal strength. Suppose you have a bidirectional antenna. Unless you're talking to two people in opposite directions at the same time, it doesn't matter if the antenna is 100% efficient and half the power goes into an unused reverse lobe or whether it goes into a resistor which makes the antenna 50% efficient. The result is exactly the same as far as the other station is concerned. So to the extent that the rhombic isn't optimal, it's because it's inherently bidirectional, not necessarily because it's inefficient.

A bidirectional antenna is usually not an optimum choice. For the same number of elements or same amount of real estate, you can usually make a unidirectional antenna which has a single main lobe of about the same width but 3 dB greater gain. Or, you can have a main lobe of about the same gain as before but greater width, which is an advantage when the antenna can't be rotated. However, this doesn't say anything about simplicity, which is the main attractiveness of a rhombic, along with its bandwidth.

Roy Lewallen, W7EL

Steve,

The MJK unit is now giving sensible results.

I changed the match from 4500 to 800 Ohms. I think the inductor Q at the
higher ratio
of impedance transform was not high enough. Matching to lower impedance
only required a Q of around 8.

Not by enough to notice on the other end. The G5RV has
a slight amount of gain over your 40m dipole. It has
low loss on the ladder-line matching section and an SWR
of less than 4:1 on the RG-213 coax. Where are the losses?

It's a 3/8WL dipole on 75m, fed with low-loss ladder-line,
a parallel door knob cap, and an SWR of 1.3:1 on the RG-213
coax. Where are the losses?

> The "usual" G5RV that most people tend to buy and run
> is one of the most pathetic 80m antennas I've ever used
> in my life.

Well, maybe. The one I bought in 1988 was well designed with
a w2du balun and RG-8x coax. It worked well with a tuner and
I made lots of improvements as I learned more about it.

There was probably something wrong with the particular G5RV's
that you have been exposed to.

Some people run a 4:1 balun at the coax/twinlead junction on
a G5RV. That's the absolute worst thing to do on 75m as the
impedance at that point is already low at 16 ohms.

Reg, I replaced my 130 ft. dipole with a G5RV so I could
experiment with it. Given my modifications, Nobody can tell
it from the 130 ft. dipole so there's no reason to return
to the 130 ft. dipole. My G5RV has an SWR of less than 2:1
on all eight HF bands.

I agree ..... the only HF wire antenna I have ever used. You have to pay close attention to the matching at 20m and then it works great. I use 300 ohm ladder line for the feed as I find that works the best. Build one and try it out ....then you can see for yourself.

==========

In the most simplistic of terms, a rhombic consists of four
1/2-wavelength wires plus a lossy resistor which gets hot.

If the four 1/2-wavelength wires are rearranged to form a dipole, plus
a reflector, plus two directors, we have only one good direction in
which 100% of the power is radiated. Nothing gets hot.

Common sense prevails. No need to refer to Eznec. Even a drunken
old-wife would know which arrangement to choose, if only because it
saves the cost and fitting of a high power, non-reactive resistor.
;o)

But no doubt US Army Field Manuals still call upon rhombics.

Reg.

The CIA W.M.D. department must have told you that naughty fib.

The SWR on your 380-ohm transmission line to the antenna is umpteen
times greater than that!

Isn't it time you changed the name of your SWR meter?

Reg.

And, in this case, I think the "most simplistic terms" are a
misapplication of the way the term is usually used.

My recollection is that in practice, rhombics of the sort being
referred to have arms which are several wavelengths long. The total
double-arm-length of a wire rhombic is often 10 wavelengths or more.

In this sort of rhombic, the great majority of the transmitted power
is radiated before it reaches the termination resistor. There is little
power left to dissipate in the resistor. If the rhombic were
unterminated, and the forward-travelling wave were reflected at the
end of the rhombic, most of this reflected power would be radiated
before it reached the transmitter and were re-reflected.

Dissipating the remaining (small) amount of forward wave at the end of
the rhombic helps maintain a very high front-to-back ratio. This can
be advantageous both when transmitting (no back-spill) and when
receiving. I believe that rhombics were popular among U.S. government
radio sites for use at coastal sites, for precisely this reason - they
were very good at rejecting QRM from landside transmitters, and didn't
blast landside receivers with high power.

Long, terminated rhombics have another advantage - they maintain a
consistent directionality and feedpoint impedance over a wide range of
frequencies... rather wider than you can do with a resonant
standing-wave antenna such as a reflector/DE/directors beam.

>Common sense prevails. No need to refer to Eznec. Even a drunken
>old-wife would know which arrangement to choose, if only because it
>saves the cost and fitting of a high power, non-reactive resistor.

If you're insisting that a "rhombic" may have arms of no longer than
1/2 wavelength, I'd agree.

Since that's not the only way to design 'em, though (and is not how
some of the better-known ones were designed), I think that your
conclusion is overbroad.

It's all a matter of serving your needs, whatever they may be. If
you're limited on space, and/or want a steerable beam, then a Yagi or
similar is probably the best choice. I certainly wouldn't try to put

up an effective HF rhombic on my roof!

If you've got oodles of space, want to listen (or transmit) only in a single direction, need a lot of front-to-back isolation, and want a broad bandwidth and consistent radiation patterns and a considerable amount of gain, then a long-armed terminated rhombic may be a better choice than the alternatives (e.e. a honking-big LPDA).

Now that is one of those things about a G5RV, no two are alike.

What are the key factors that "define" a G5RV? The things that I recall from Varney's article were:

- 31m long dipole
- centre fed
- flat top / inverted V
- open wire section of half wave length on 20m, from his physical description, Zo about 520 ohms, but IIRC he suggests Zo is not critical
- undefined length of either coax of open wire line of undefined, but low Zo (50 - 120 ohms though he seemed to think figure 8 flex has a lower Zo than it probably does).
- balun or no balun at the coax to open wire line transition, depending on his article, he changed his mind.

My question is how many of these characteristics can be dispensed with, or varied significantly and still legitimately speak of it as a G5RV?

I am watching the argument between those who swear by a G5RV and those who swear at a G5RV and suspect that one of the reasons (and not the only reason) is they are not talking about the same thing.

There is a tendency to call anything with a ~30m centre fed dipole a G5RV, and yet that component's pattern is independent of everything else (excluding feedline radiation) and its efficiency is quite good independently of everything else. It is "everything" else that contains the losses that result from the dipole's feedpoint load impedance, and it is the "everything else" that makes or breaks the antenna.

Thanks for the input, but my tower is tapered and by the time the hazer moved from bottom to top there would be too much slop. That is why I need some sort of rail system.

> Depends what you compare it to... I bet my paralleled
> 80/40/20 dipoles would beat it on all those bands.

>Not by enough to notice on the other end.

So you say. If I can tell the difference between a tuner/
ladderline fed dipole vs a coax fed dipole, I bet I could
tell the difference. But I use the receiver, and switch
between the antennas. Much more accurate than
relying on reports.

>The G5RV has a slight amount of gain over your 40m dipole.

That just means I'm almost sure to be louder in the
other two directions.. :/

>It has
>low loss on the ladder-line matching section and an SWR
>of less than 4:1 on the RG-213 coax. Where are the losses?

At the ladderline/choke/coax junction I would suspect.

> You would be the exception to the rule. And I still really doubt
> it's the total equal of a simple coax fed dipole on 80m.

>It's a 3/8WL dipole on 75m, fed with low-loss ladder-line,
>a parallel door knob cap, and an SWR of 1.3:1 on the RG-213
>coax. Where are the losses?

Does that version use the choke? Being the data is incomplete,
hard to say at this point. But if there is loss, I can probably
find it.. :/

> The "usual" G5RV that most people tend to buy and run
> is one of the most pathetic 80m antennas I've ever used
> in my life.

>Well, maybe. The one I bought in 1988 was well designed with
>a w2du balun and RG-8x coax. It worked well with a tuner and
>I made lots of improvements as I learned more about it.

Hummm...Does that mean it's not really a G5RV anymore?

>There was probably something wrong with the particular G5RV's
>that you have been exposed to.

No doubt about it.

Some people run a 4:1 balun at the coax/twinlead junction on
a G5RV. That's the absolute worst thing to do on 75m as the
impedance at that point is already low at 16 ohms.

I bet those did use a 4:1...Kinda makes sense as they were
the absolute worst wire antennas I'd ever used on 80m.
But like Owen points out, you have so many perversions
of the G5RV, it's hard to tell what is what. I *think* the
versions I used were made by the same company that
makes the carolina windoms, but not sure. I don't
really keep up with antennas I know I'll never be using.. :/
What boggles my mind is why people would want to use
a compromise antenna at a field day, when you have
enough room to fit 49 full size antennas... :/
Or at home for that matter.. If I have room for full size
antennas, I'm gonna use them. Life is too short for
compromise antennas. I guess I'm spoiled. I've never
had to run those funky things due to lot size, etc..
Even if I did, I think I could cook up something better
than the usual G5RV. Whatever I use will never mix
feedline types midroute to the antenna, I know that
for sure. It's like a crapshoot hoping things will pan
out at the junction. I couldn't live that way. :(

I'm not talking about SWR on the series section transformer,
Reg, I'm talking about on the 50 feet of RG-213. And it's
not "umpteen times", rather limited to about ten times.

> Isn't it time you changed the name of your SWR meter?

Nope, for a G5RV with the nominal 70 feet of 50 ohm coax,
the SWR meter is indeed reading the SWR on the coax.
Remember, I'm not using a tuner. The coax from the G5RV
goes directly to the transceiver through the SWR meter.
I actually use my SWR meter to display the SWR.

Well, with G5RV himself recommending ladder-line all the way
to the transmitter (ARRL Antenna Compendium #1) "If this form
(of the G5RV) is employed, almost any length (of balanced line)
may be used from center of the antenna to the matching network
(balanced) output terminals", the paintbrush is pretty broad.

I started out with a standard G5RV and modified it on a per
band basis to perform on all eight HF bands. 36 ft. of ladder-
line works on both 40m and 17m, my two favorite bands. When I
switch to 75m, I use 23 ft. of ladder-line with a parallel
1000pf cap. I call that the *PC-50* point, the point at which
a (P)arallel (C)apacitor will cause a match to (50) ohms.

The only thing there that could be lossy would be the choke.
Why would a 1000 ohm choke be lossy?

Yes, but the impedance at that point is very close to 50 ohms
and the choke has about 1000 ohms of choking impedance.

Not a crapshoot at all - just an application of a series section.
Do you object to 1/4WL of 75 ohm twinlead feeding a full-wave loop?

I have both a 130 foot dipole and a G5RV, I can switch between the two and the reports are exactly the same on 75. With 100 watts on the G5RV I have worked well over 100 countries on SSB 75 meters. The day I received the Olivia for my mix w, worked Russia on it with 5 watts on 20 meters.

I use it nightly on my Navy Mars nets in the 3 Mhz area.

Like the 130 foot dipole I vary the feed line length to tune.

Both feedlines are fed from the rig to the ladderline with coax covered with ferrite beads at the junction end.

What??? Four 1/2 wavelength wires!! You gotta be kidding!!!

The Rhombic at AGA5HI in the early 70s was close to 6 wavelengths per side.

There are/were two different rhombic designs. [Roy may want to comment
on this.] A resonant rhombic without a termination resistor is
bidirectional. A non resonant rhombic, a traveling wave design that uses
a terminating resistor is unidirectional.

Gain increases as the length of each side increases. Directivity [gain]
is also dependent on the included angle which contributes to radiated
beam width.

==========

I see you are happy to change names when in a tight corner.

The name "Transmission line" has been conveniently changed to "Series
Section Transformer".

But it still has standing waves on it far higher than what you claim
for all bands. And don't standing waves increase loss on SST's just as
much as they do on transmission lines?

Louis is turning over in his grave - yet again.

But what the heck? A G5RV will work even if you havn't got one.

I once set up an 80 feet dipole without a series section transformer.
Unsurprisingly - it worked. ;o)

Reg.

Yes and, being open-ended, is a *standing-wave* antenna.
Contrary to what has been said here on r.r.a.a in the
past, Balanis says: "The current and voltage distributions
on open-ended antennas are similar to the standing wave
patterns on open-ended transmission lines. ... Standing
wave antennas, such as the dipole, can be analyzed as
traveling wave antennas with waves propagating in opposite
directions (forward and backward) and represented by
traveling wave currents If and Ib in Figure 10.1(a)."

As you know, standing waves increase loss on SST's just as much
as they do on transmission lines *OF THE SAME LENGTH*. For instance,
on 3.8 MHz, that 300 ohm series section transformer on a G5RV has
an SWR of about 20:1 and a line loss of about 0.7 dB, about 12% of
one S-unit. That's a small price to pay for multi-band operation.
And using Wireman #554 (like I do) instead of 300 ohm twinlead will
cut those SST losses down to 0.37 dB, about 6% of an S-unit.

> I once set up an 80 feet dipole without a series section transformer.
> Unsurprisingly - it worked. ;o)

If you fed it with ladder-line, you fed it with a long series
section transformer. :-)

Why would that be of any advantage? Do you believe it is easier to solve for the exact radiated fields by partitioning the standing wave into two components?

The real challenge in antenna theory is determining the exact current distribution. Further subdividing or superposing the current is a trivial exercise in comparison, and such manipulation may or may not be useful.

In other words, what Balanis says may be true, but so what?

73,
Gene
W4SZ

If the unterminated rhombic is long enough to be considered a -real-
rhombic, it is both a standing wave and a traveling wave antenna.

If you want to think of it in transmission line terms, it's a very
lossy line. The 100% reflection at the open end is 100% of what's
left after the effects of resistive and radiated loss are factored in.

The rhombic as the positive attribute of simplicity but that is about
the only positive. It takes a huge amount of space (in wavelengths)
and it's really a crappy antenna from the standpoint of minor (and
some not so minor) lobes. The Laport version is much better, but much
more complicated.

The "so what" is the additional knowledge to be gained by
not choosing to ignore the underlying physics. When the
forward EM wave hits the end of the dipole, what happens?
Essentially the same thing that happens when a forward EM
wave hits the end of an open-circuit transmission line.
The H-field (current) goes to zero and the E-field (voltage)
doubles, i.e. the forward wave existing at that point is
completely reflected.

That explains why the feedpoint impedance of a 1/2WL dipole is
50-75 ohms instead of the physical characteristic impedance
of ~1200 ohms. The feedpoint impedance of a 1/2WL dipole is
a virtual impedance caused by destructive interference
between the forward and reflected voltages, Vfp = |Vfor|-|Vref|,
and constructive interference between the forward and reflected
currents, Ifp = |Ifor|+|Iref|, and Zfp = Vfp/Ifp

It is interesting to note the consistency of the arguments
here on r.r.a.a. Someone says, "'A' is true". Someone else
says, "No, 'A' is gobbledygook". After 'A' is proven to
be true, the argument shifts to, "OK, so what? Those grapes
are probably sour anyway." :-)

Cecil,

I don't understand the "sour grapes" reference. To the contrary, I
believe I have argued with you many times that there are multiple ways
to solve a problem.

Use standing waves or traveling waves as you choose for computational
convenience. The only thing that goes into the field-defining equations
is the current, not the waves.

Your original message implied that may be some special benefit to a
standing-wave antenna over a *non-standing-wave* antenna. Other than
all of the hand-waving, which seems to somehow be connected to your
intuitive thinking, there is no physical difference.

>Not a crapshoot at all - just an application of a series section.

I'm not really talking about yours though. I'm talking about
the "usual" G5RV that is fed with a tuner, etc, ad nausium.
Most people don't change sections when they change
bands. They just redial the tuner and go.
If you change very much with a G5RV, it's not a G5RV
anymore. IE: If you feed a 102 ft dipole with ladder
line, but no choke or coax, it's not a G5RV anymore.
It's a 102 ft dipole fed with ladder line.
A series transformer for a loop is not quite the same to
me as it's almost always a single band solution.
I won't be expecting that transformer to work for all bands.
Like I said, if the "G5RV" or others of it's ilk are appealing
to you, be my guest. But trying to talk me into using one,
or even accepting it as something I would actually use is
futile. :/
Tell me this...What is the advantage of using the choke,
coax, etc, vs just running straight ladder line the whole
way? If I had to tuner feed a 102 ft dipole for all bands, thats
the way I would do it. There would be no coax, or choke.

Is this the antenna described at http://www.qsl.net/w5dxp/G5RV.HTM ?

In that article, on 75m you model a feedpoint impedance of 36-j324,
28' of 300 ohm ladder line, for a Z of 15+j4 (seems to indicate 46.7
deg length of 300 ohm line with 0.007dB loss (optimistic)).

At that point, were 50 ohm coax connected directly, the VSWR at the
load end of the 50 ohm coax would be 3, however you shunt the 17+j4
with 1000pF to give a new Z of 12.5-j8 that results in a VSWR at the
load end of the 50 ohm coax of around 4.1, driving a little more loss
into the coax section.

Presumably when you say that the capacitor improves the VSWR on 75m,
you mean the VSWR on the coax. Did I miss something, how does the
capacitor improve the VSWR on 75m?

Owen

PS I couldn't make the numbers work for 22' as in your quote, where I
got a VSWR at the load end of the coax of 27. I couldn't see where the
VSWR of 1.3 comes from?

>I have both a 130 foot dipole and a G5RV, I can switch between the two and
the reports are exactly the same on 75. With 100 watts on the G5RV I
have
worked well over 100 countries on SSB 75 meters. The day I received the
>Olivia for my mix w, worked Russia on it with 5 watts on 20 meters.

>I use it nightly on my Navy Mars nets in the 3 Mhz area.

>Like the 130 foot dipole I vary the feed line length to tune.

Hummmmm.......... :/

Both feedlines are fed from the rig to the ladderline with coax covered
with
ferrite beads at the junction end.

Try the 130 ft dipole fed with straight coax and see if you don't
see a difference then. Sure, it won't be huge, but it should be
there, and be quite noticable too on a receiver. I think this why you
are seeing no difference. .
You are "clutter" feeding both antennas. :/ Seriously.
Coax to ladderline...yuk...:/
But saying that, it's obvious it works well nuff I suppose..
I just like to stir it. It's been too slow around here lately.
But...I am serious about what I say.. If you want the vurry
best 80m dipole, feed it with nuttin but coax.

>Is this the antenna described at http://www.qsl.net/w5dxp/G5RV.HTM ?

I have made a mistake during my analysis, let me try again:

In that article, on 75m you model a feedpoint impedance of 36-j324,
28' of 300 ohm ladder line, for a Z of 15+j4 (seems to indicate 48.2
deg length of 300 ohm line with 0.007dB loss (optimistic)).

At that point, were 50 ohm coax connected directly, the VSWR at the
load end of the 50 ohm coax would be 3, however you shunt the 17+j4
with 1000pF to give a new Z of 17.3-j3.0 that results in a VSWR at the
load end of the 50 ohm coax of around 2.9, almost identical to the
case without the capacitor.

Presumably when you say that the capacitor improves the VSWR on 75m,
you mean the VSWR on the coax. Did I miss something, how does the
capacitor improve the VSWR on 75m?

Owen

PS I couldn't make the numbers work for 22' as in your quote, where I
got a VSWR at the load end of the coax of 27. I couldn't see where the
VSWR of 1.3 comes from?

How about someone who simply doesn't LIKE alcoholic drinks? :) I've had a
sip of a beer twice in 15 years. Like some that don't like broccoli, I don't
like liquor. It all tastes horrible to me and I'd rather have a unspiked
Coke! It all tastes the same to me----Nasty! YUCK! BARF! The Coke tastes

sweet and, when I drive home afterwards, I know where home IS and can get there unassisted! The only "bad" effect from a Coca Cola is, it makes me have to pee! :) After 57 years, I think I can do without for a few more. Now the broccoli? I love broccoli casserole!! ;)

So, what about Radar then...

First, There are two "kind" of RF radiation, non-ionizing and ionizing and effects emanating from very high voltage nearby different materials.

Normally, non-ionising is to be more or less compared to sun light.
An overdose of non-ionising radiation gives the same effects than sun stroke gives you, you heat up your body and the same symptoms occur if overheated.

As long as you are not overheating, there should be no harmful effects on you. The problem are always to determine a narrow angle beam, radiating towards sensitive parts of the body, like brain and eyes. The long term effects of a heated brain are probably still debated. However, it's probably not good for you. A narrow angle beam does not give the same full body heating that "switches" your body reaction as it's only a part of you that gets overheated, not the whole body!
If you are stupid enough to look into a wavegiude with full power on, be my guest!

Now then to the nasty part, the ionising radiation. This radiation creates residual effects even after the emitted radiation is switched off.

Typically radiation like Gamma radiation etc. This kind of radiation could also create secondare types of radiation from materials in the environment.

Treat the ionising radiation like plague or cholera, avoid avoid avoid.

Now, radar radiation is only non-ionising RF radiation, let be with high intermittent power and sometimes with stupidly high power.
Looking into an active waveguide will probably burn off your eye nerve or something very bad for you.

If you are standing near a RF radiating radar station, the average energy is what heats you up and the peaks are so short that even if they are Mega Watts, the average energy transfer to your body is low.

Going up in frequency more or less moves the RF towards light, still with the same effects.

OK, so it's not that bad is it? No? Wrong! Some frequencies are really bad for us because different parts of our bodies absorbs different amount of energy on different frequencies.

Let's take a party example... Many key fobs, alarm buttons for car locks etc, operates on 418MHz. It happens to be approximately where a normal head are resonating... Try walking just about out of range for your alarm/lock button for your car, point the key fob against your head and press the unlock key, voila, in most cases, you increase the range of the key fob.

So what? Just be aware and take a look in the health and safet chapter of the ARRL handbook. It's all there and also how much more dangerous it is with different frequencies.

The safest place are almost always under an antenna so don't fret over the mobile phone mast on the roof of the school! I would be more concerned if it was on a neighbouring house...

Cheers

Dan / M0DFI

Actually, you have gone from saying I was wrong to saying that I am
right but it doesn't matter. I guess that's an improvement. :-)

> Your original message implied that may be some special benefit to a
> *standing-wave* antenna over a *non-standing-wave* antenna.

Sorry, I never said anything about a standing-wave antenna having some
special benefit over a traveling-wave antenna. It was a problem with
the inferrence function, not with the implication function. :-)

The ARRL Antenna Book has details in CH. 8 on multi element driven arrays. I don't know if there is a project available on the internet. I have never built a W8JK array, although they should not be that difficult.
Why do you want to build an 8jk, and for what band? Does it fit your particular application, or do you just want to experiment? Just curious.

> way?

The advantage is a pretty good match on 80m, 40m, 20m and
12m that's not guaranteed with straight ladder-line. Some
lengths of ladder-line present additional problems. For
instance, if one happens upon a current maximum point
located at a 4:1 balun, one can take 16 ohms down to 4
ohms. That's going in the wrong direction.

Well, I'll put the system I started to design last night up against most
other 80m antennas. But it won't be cheap to build. Needs 8 165-foot
towers, and a bunch of phase delay networks and some power dividers. :-P

But the gain over ordinary ground works to between 9.5 and 10.5 dbi
depending on the direction favoured by the phasing networks.

Nope, that's just an off-the-shelf vanilla G5RV.

> In that article, ...

Forget that article which only shows why the *standard* G5RV is
a fairly well matched antenna on 80m and 40m.

> Presumably when you say that the capacitor improves the VSWR on 75m,
> you mean the VSWR on the coax. Did I miss something, how does the
> capacitor improve the VSWR on 75m?

I'm sure you know this already. Given an SWR circle on a Smith Chart
that crosses the horizontal resistive line at less than 50 ohms and
given the 1/50 conductance circle, those two circles will cross at
two points. Where they cross in the capacitive reactance region is
the point on the transmission line where a parallel capacitance will
bring the impedance at that point to 50+j0 ohms. This is a common
matching technique for 75m mobile antennas. The same thing can be
done with a coil installed where the circles cross in the inductive
reactance region. This technique is described in the ARRL Antenna
Book.

What I have done on my G5RV is find the point where the SWR circle
intersects the 1/50 conductance circle in the capacitive reactance
region on 3.8 MHz and install a 1000 pf parallel cap there. My series
section line is 22.5 ft. of Wireman #554 at that point. The 50 ohm
SWR is reduced from about 5:1 to 1.3:1 on 3.8 MHz.

Given an SWR circle crossing the 1/50 conductance circle, there's a
point where a cap will result in 50 ohms. A little farther, a cap
will result in 300 ohms. A little farther, a cap will result in
450 ohms, etc. These are the points just past the current maximum
point where one can hang a capacitive stub to achieve a purely
resistive impedance.

There's nothing wrong with a G5RV if you couple power to its radiating
element efficiently. I usually just don't bother with the coax part of
the feed system and prefer to just run 300 ohm (or better yet 450 ohm)
line right to the shack and feed it through a tuner.

Well, as a data point, Owen's transmission line loss calculator says there's 0.362 dB loss in 100 ft. of RG-213 feeding a 50 ohm antenna on 75m. The loss using 100 ft. of open-wire feedline feeding a 50 ohm antenna on 75m is 0.169 dB, less than half the loss in the coax. Even the Wireman #554 "450" ohm line is better than the coax at 0.269 dB. Where are the losses in a Ladder-Line fed system?

> you mean the VSWR on the coax. Did I miss something, how does the
> capacitor improve the VSWR on 75m?

What you missed is that the frequency must be changed to obtain the
benefit. The capacitor is *not* installed at the 17+j4 point. It is
installed at the 1/50 + j1/X admittance point. You can either increase
the length of the feedline past the 17+j4 point to the 1/50 + j1/X

admittance point or increase the frequency thus electrically lengthening the feedline to the 1/50 + j1/X admittance point. You cannot keep both of those values constant as you tried to do above.

You already know what I am trying to say. I must not be saying it very well. When a parallel cap is used on a 75m screwdriver antenna to achieve 50 ohms, the screwdriver is tuned to 1/50 + j1/X, i.e. slightly inductive. When a parallel coil is used, the screwdriver is tuned to 1/50 - j1/X, i.e. slightly capacitive.

But... in that article which recommends 28' of 300 ohm ladder line you say "To improve the 75m SWR, try installing a 1000pF capacitor (mica or doorknob) in parallel across the ladder line at the ladder line to coax junction. Remove the capacitor for all other bands."

IMHO, just considering in isolation what is shown on that page there is something inconsistent about the Smith chart, the impedances, lengths, and assertions about the SWR improvement.

...

>What I have done on my G5RV is find the point where the SWR circle

>SWR is reduced from about 5:1 to 1.3:1 on 3.8 MHz.

This implies you are trying to "tune out" the shunt capacitive reactance at a point on the line where the shunt resistive component is 50... but you need the opposite sign of reactance reactance (so that the susceptances subtract), you need an inductive reactance in that case.

If "your G5RV" has a feedpoint impedance of 36-j324 (that seems reasonable), your 22.5 ft. of Wireman #554 will transform that to 21.53-j53.33, and the VSWR in 50 ohm line connected at that point would be 5.3.

A shunt capacitance CANNOT improve the 50 ohm VSWR at that point

The effect of the shunt 1000pF capacitance is to change the impedance at the junction to around 3.6-j25, which would cause a VSWR of around 17 in the 50 ohm line.

However:

If the ladder line was around 31' in length, then the Z at that point would be around 21+j25 (equivalent to 50 ohms R in parallel with +43 ohms X), and a shunt 1000pF (~ -42 ohms X) capacitor would give nearly perfect VSWR on the 50 ohm line.

In summary, in a general sense, if you want to use a shunt capacitor as you propose, you need to find length of line such that the admittance at that point is 1/50-jB (negative susceptance is inductive), and the correct shunt capacitor has a reactance of 1/B.

Flawed explanation aside, the only way that 22.5' works is if your feedpoint Z is quite different to 36-j324.

Negative susceptances are inductive. An inductive reactance of j5 is a
susceptance of 1/j5 or -j1/5.

I agree with your words, the sign of the admittances is wrong.

The diagram is not clear, is it.

The basic End-fire W8JK uses two half wavelength dipoles spaced an
eight of a wavelength. It has a half twist of the openwire line
between the dipoles, and it is fed at the centre of that line.

So, for 20m, each of the two dipoles will be about 10m long (end to
end), and they will be spaced about 2.5m apart.

(The diagram might lead you to think that each half of the dipole is
around 10m, but that not correct.)

Thanks for explain the diagram.
But now i have another doubt.
i have found on cebik home page an example of w8jk antenna.

You can seee at http://www.cebik.com/fdim/fdim9.pdf on page 6 and 7

in this project the full element is 44'(13.2m) but spacing is 22'
(6.6m)
So in this case the element is longher than 1/2wl (i'm also reading
that the optimum is that the full element is from 1wl to 1.25wl, so
from 20m to 25m) and spacing is between 1/8 wl to 1/2wl.

What is the best choise?
If element is to short i may have very low impedence

"If" is the important word. My G5RV is obviously different from your
values. It's made out of insulated wire and I'm not sure it is exactly
102 feet long.

> Flawed explanation aside, the only way that 22.5' works is if your
> feedpoint Z is quite different to 36-j324.

And it is obvious that's the case. The "450" ohm ladder-line is 22.5 ft.
long and a 1000 pf capacitor resonates it on 3.8 MHz. Whatever the
feedpoint impedance needs to be to cause those conditions, that's
what it is.

Yes, you are correct - sorry. But it now seems that you understand
what I was trying to say. If one takes an ordinary G5RV and
installs a parallel 1000pf capacitor at the coax/twinlead junction,
one will raise the resonant frequency and lower the SWR on the
coax for 75m operation. Very close to 50+j0 ohms can be achieved
on 75m through that simple act. When I lived in AZ, I switched that
cap in automatically using a relay and the frequency output signal
on my IC-745.

Source record: 65473

Just read all msg on the g5rv question (wow) so let me introduce my problem - I bought a shorty forty 2ys ago at a hamfest, now Im ready to use it:

I have two poplar trees about 150ft fm house about sixty feet apart (perfect) and a garden shed underneath almost centered. The shorty forty is fed with (not measured) twin lead with a female coupler for a pl259 to get to house. I have about 180ft of catv (75 ohm) . Question: should I use a 6 to 1 balun attached to shed or should I just attach the catv to the ladder line and let it go. The vendor of the shorty forty assured me that I just had to attach normal 50 ohm coax to the connector and I was ready to go. of course I have a good tuner and used it many years with a van gorden g5rv and did great but the van gordon came with a balun at the end of the twin lead.

thanks - george

Forget the 6:1 balun - install a 1:1 current choke-balun
at the coax/twinlead junction. The W2DU type works well.

>Where are the losses in a Ladder-
>Line fed system? ....

The tuner that is usually used offsets the advantage
of the line itself. Sure, on paper you shouldn't really
be able to notice it. But I do when I test it. It's actually
measureable on an S meter when doing A/B comparisons.
Or at least it was for me when using a 989c tuner
and minimum inductance vs coax fed.
That tells me the tuner loss can often be a bit more
than it's cracked up to be. But I also found if you don't
use the minimum inductance when tuning the tuner,
you can lose quite a bit. I saw easy 20 % losses when
testing that one time. If I used the very least inductance,
I could get it down to an almost unmeasureable level.
If I get on 80m and want the very best efficiency I can get
feeding a dipole, I use coax.
Of course, the line is never more than 100 ft.
Usually more like 50 ft. I have a 50 ohm radio feeding a
low loss 50 ohm line, to a 50 ohm antenna feedpoint. You
have uncluttered perfection. :-) And in the real world
the most efficient that I've seen so far. If there was better,
I'd be using it. I could see using the ladder line on real
long distances. On the higher bands, it could be noticable.
But like I say, my run is about 50 ft. Considering efficiency
vs ease of use, wx resistance, ease of lightning protection,
coax is a no brainer for me. Of course, I ain't everyone.. :/

>Tell me how to coax feed a dipole that works from 3.3 to 4.1 MHz and you
>have my attention.

Probably wouldn't be practical for you.. Just offhand, I can think
of a way, but you'd have to run at least two set of dipoles, and
maybe even three, tied together in parallel. You would stagger
tune them one low, one middle, one high, and the SWR
plot should look about like a \/\/\/ . I've never tried using
three dipoles, but I've done it with two and having a W SWR
plot. That is one way you could have that range and use
coax feed. But like I say, probably would be a PIA with
it needing at least one center support and six tie off
points.

Source record: 65378

Hi, all concerned:

The W8JK antenna can keep its same general broadside pattern when the lengths and spacing vary widely. So, you can build one to fit the space available, and you need to pay attention only to keeping the 4 lengths of element-wire close to the same length, and to crossing the phasing line over between element feedpoints**. It will work well over a 3-to-1 frequency range.

Element maximum-currents and voltages can be quite high, so use the largest practicable wire size, and good insulators.

Exact lengths or "resonance" do not seem to affect patterns. It is probably easier to use open-wire feedline. To make the antenna easier to tune, you can vary the feedline length between the transmitter and the antenna. Make your feedline "tune the antenna".

Modeling it with EZNEC shows that, at lower frequencies, it can have more radiation at lower angles than some other simple antennas at the same height above ground, and that shifting the feedpoint away from the center of the phasing line produces a uni-directional pattern.

I hope this helps.

OK.

I played around a bit using the feedpoint impedances that I modelled for my "Feeding the G5RV" article. With 31' of 554, I needed about 2000pF to "tune" it for low 50 ohm VSWR at 3.6MHz.

I plotted the impedance presented to the coax for a range of frequencies from 3.5 to 3.8MHz, they are at http://www.vk1od.net/temp/G5RV-W5DXP.GIF . The Smith chart is normalised to 50 ohms. The solution seems fairly narrow band, the VSWR at 3.55 was 6, at 3.6 it was 1.3, and at 3.65 it was 5.

Of course, implementations will have slight differences in actual feedpoint impedances, and the outcome is very sensitive to slight differences in feedpoint Z. This "no-tuner" matching scheme will probably need significant customisation for each implementation.

==========
The World-famous G5RV.

What everyone appears to forget, is that Zo of the balanced twin-line section, on all bands except at 14.15 MHz, has a considerable affect on feedpoint impedances, swr, losses, etc.

When describing systems and performance nobody ever mentions what Zo of the feedline actually is. Omission of Zo reduces any following discussion to blythe, innocent nonsense.

R.L.Varney himself never gave a value to Zo. He didn't need to. He was concerned mainly with 14.15 MHz. It would be unfair to accuse him of not understanding the serious effects of Zo on other bands.

Reg.

420. Inverted-L Antenna And Close Proximity Coax ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-11 12:40:52 UTC
From: Robert11 <rgsros@notme.com>

Source record: 65381

Hello:

Planning on putting up an outside Inverted-L antenna.
Listening only.

Looks like I will be stringing the vertical section along the
house side (an inch or two off of the wood on some kind of standoffs) to the top, where it
will begin the horiz. section to a nearby tree.

At the bottom of the vertical section, a foot or so off of the ground, I plan on burying a long length of copper
tubing for a ground, and probably an ICE lightning protector (to the same ground point).

A Balun and a start of the coax run to the receiver also starts at this bottom point.

Question:
The easiest way by far for me to get the coax to the receiver is to run it up from the Balun to my second floor where the receiver is.

If I run it upwards "right alongside" (or even tied to) the active vertical section of the antenna, will I have any problems ?
Remember, this would be coax, and I do receiving only.

Guess I'm worried about if the grounded shield of the coax presents some kind of ground element right next to the active element ?

Thanks,
Bob

Source record: 65382

David weote:
"How do you get an omni-directional pattern from this antenna?"

In a point to multipoint system, only the central station needs an omni antenna.

One orderly radio data acquisition system operates half-duplex. Only one station at a time transmits, and then only when called upon to do so.

A radio master interrogates remote stations within its reach, addressing them by name, rhen listens for their response. Only a single radio frequency is needed as remote stations don`t initiate transmissions until callef upon. In this master-slave relationship, there is no competition within the system for radio time.

The radio master can conveniently use an omnidirectional antenna as it communicates with slaves on various azimuths. The slaves only communicate with the master, even to communicate with each other. The slaves each have a directional antenna aimed at the master.

A directional antenna improves signal to noise ratio when transmitting and when receiving. Great gain and directionality, though desirable, may be necessary only when very low transmitter power must be used..

The long-boom directional loop array may have a gain of 20 dB. But, a 3-element Yagi can give a 5 dBd gain which may be plenty. This gain is almost equivalent to cutting the path length by half (6 dB).

The Yagi is close-spaced. With only 3 elements it is small and simple to build.

Normal narrow-band receivers are very sensitive so that very weak signals are sufficient if noise and interference are not severe. Higher gain antennas can be used as needed at remote sites on a case by case basis.

I built such a system decades ago and it is still in use.

Best regards, Richard Harrison, KB5WZI

I'm just reporting what it took for my actual antenna under the
existing conditions at my QTH. The cap is actually 950 pf for
a minimum SWR of 1.3:1 on 3.9 MHz. The optimum value of the cap
would no doubt change at lower frequencies. With 22.5' of
Wireman #554 and a 950 pf cap, the 3:1 bandwidth is 145 kHz.
Adding sections of ladder-line lowers the resonant frequency.

Incidentally, this is a method for modifying the G5RV to work,
not only without a tuner, but with built-in tuners. When using
a built-in tuner, the antenna configuration doesn't have to
be changed as often. My IC756PRO will tune my present configuration
from 3.72-4.0 MHz. or 280 kHz.

> I plotted the impedance presented to the coax for a range of

Changing the length of the series section will shift the resonant
frequency. I can vary mine from 22.5 ft. to 38.5 ft for a near-
perfect SWR on all HF ham frequencies.

Hi Bob,

There is no inherent advantage in the inverted L except it being a top loaded vertical with some horizontal polarization properties (being unbalanced and all). You can save yourself some bewilderment by driving the bottom directly into ground and simply connecting your coax right at your second floor window with the coax shield connecting to the wire going down, and the coax center to the wire going up and to the tree. When lightning suggests itself, unconnect the coax from your receiver and drop the coax out the window.

You will never notice the proximity of the wood siding, but you may notice the proximity of house wiring that is in that wall. That wiring may be carrying house noise (like a computer's monitor's hash). However, that is best left for future investigation instead of paralyzing you now.

Also, build an antenna tuner, or buy a very cheap, no-meter 3-knob Ham tuner (less than $30). When you get into better antennas, you get into overdrive possibilities from nearby AM stations (and I bet there are a bajillion there in Mass). This is called "desensing" when those stations (even when you are not tuned to them) overpower your radio and drive the AGC so high, that you cannot hear weaker DX in the SW bands.

==========

Cec, the facts are, G5RV never mentioned Zo, either because he never attached any importance to it, or he didn't understand its relevance to other bands.

When considering other than 14.15 MHz perhaps he should have done. In any event, everybody else has followed suit.

Now we have the situation where dozens of people are busily seriously comparing all-band versions, one with another, and unknown to each other they are all using different value Zo transmission lines.

Many of those who purchased the antennas, or just copied G5RV's construction, havn't the foggiest idea what their particular Zo is. Yet, from an analysis point of view, which you are involved with, it is a crucial matter.

Your own Zo is a non-standard 375 ohms because you measured it. Yet you describe its performance to others as if everybody else's Zo is the same, whereas there is no hope of anybody else reproducing your particular results.

Its all a load of nonsense!

If anybody, at this very late stage in the art, should still wish to acquaint themselves with the less than mediocre performance of a G5RV, then download program DIPOLE3 from website below.

DIPOLE3 is a general purpose program which deals with a dipole of any length, at any frequency, plus balanced-twin feedline of any length and any Zo, plus balun, plus coax line of any length and Zo, plus L-tuner. So it happens to include a G5RV.

All the data for the original G5RV can be inserted in the program by depressing one key. Modifications to the system, such as changes in Zo, can easily be done and changes in performance immediately seen.

The final important output figure is overall loss between transmitter and radiated power. Individual losses in the antenna, in the two transmission lines, and in the tuner, are reported seperately. Even the tuner L and C settings and their circuit locations are predicted.

It is very easy to sweep over the HF frequency range to check when low swr happens to fall into amateur bands. (Unfortunately it doesn't do this very often.)

It is also easy to change the length of transmission line (as Cecil recommends and advertises) to try to obtain an swr of less than 2:1. But you can use any dipole length other than 102-feet to play with this useful aspect.

Accuracy is better than needed for the intended purposes and is generally as good as the accuracy of program input data. There is only one known trivial bug which occurs when dipole length is extremely short compared with wavelength. But clearly this is not of consequence.

What more could you want from a G5RV? There's nothing to do but erect it and then compare it with a dipole of any other length with an open wire feedline of thick wire, of no particular length, all the way to the shack. Plus a choke balun.

I'm still on Red, South African, Western Cape.

Download DIPOLE3. Its free to USA citizens.

Now Reg, you know that most statements using the word "never" are false. Here's a quote from G5RV, himself, from "The G5RV Multiband Antenna ... Up-to-Date" in The ARRL Antenna Compendium, Vol. 1.

"If you decide to use 300-ohm ribbon type feeder for this (series) section, it is strongly recommended that the type with 'windows' be used. ... Since the VF of standard 300-ohm ribbon feeder is 0.82, the mechanical length should be 28 ft. However, if 300-ohm ribbon with windows is used, its VF will be almost that of open-wire feeder, say 0.90, so its mechanical length should be 30.6 ft."

Unless a self-respecting radio amateur wishes to set up a
point-to-point communications link, he would not consider a rhombic
which wastes half the transmitter power in a resistor.

How popular are rhombics, such as you describe, amongst amateurs?

There are, of course, some rich, perhaps contest participating
amateurs, with time any money to burn. I have no objection to their
existence. They are very welcome to the fraternity. They demonstrate
just what can be achieved.

Reg.

Now Cec, your reference to my use of the English language, which you well understand, is an admission that you have lost the argument - whatever that may be.

And you, more than most people, should realise that it's fatal to use ARRL publications as Bibles.

The facts are, the Zo of the G5RV trannsmission line is indeterminate. Everybody has a different but unknown value.

And it follows that, so are all the interminable discussions on the subject which take place on this and other newsgroups. Hardly educational. They approach amusing nonsense!

But no doubt you will wish to further dig yourself in and have the last word. Go ahead! ;o) <smiley>

>and minimum inductance vs coax fed.

You are telling us that you have evaluated the loss of a MFJ-989C antenna tuner + open wire line vs coax by on air A/B tests using the S-meter as your indicator.

Presumably you used exactly the same antenna, how are you sure that the feedline wasn't an active part of the antenna, was the measurement made over an ionospheric path, was the A/B comparison made at different times when other things may have changed?

What would be your confidence limits on such a experiment?

If you recorded your results, the variance would be revealing.

I suggest that the noise in your experiment would probably swamp the true difference between your A and B configuration, and therefore your conclusion might not be sound.

Your observation is (as you note) different to "on paper" expectations, that might be reason to re examine the experimental setup in search of an explanation.

> . . .

I don't think you'll see both those effects (lower radiation angle and unidirectional pattern) at the same time.

You'll find that the elevation pattern of small to moderate sized Yagis, log periodic antennas, and most other horizontal arrays is essentially the same as that of a dipole, at least at the lower elevation angles. The reason is that most horizontal arrays have a broad free space pattern in the vertical plane -- not that much different than a dipole, in the forward array direction. The W8JK is unusual in that respect. Its free space vertical pattern is noticeably narrower than most other moderately sized horizontal arrays, so it has a narrower elevation pattern when mounted over ground, too. The net result is a greater concentration of radiation at lower angles.

Unfortunately, the cost of this narrower vertical pattern is a bidirectional horizontal pattern, resulting in half the applied power being wasted unless you happen to be talking to two oppositely-located people at once. So for a given power input, the gain is 3 dB less than a unidirectional antenna with the same lobe width, or the same as a unidirectional antenna with a considerably wider lobe. The only way to fairly compare the gains is by modeling and looking at the field strength of the antennas at the azimuth and elevation angle of interest. (Loss must be realistically included in the models, too.) It's entirely possible that the advantage of concentration of radiation at lower angles is more than offset by the lower gain due to its bidirectionality and/or loss (see the next paragraph). Of course, you can change the feed as Dave suggests to get a unidirectional pattern. But then your free space elevation pattern becomes a broad cardioid, and you end up with a dipole-like elevation pattern over ground.

Among the advantages of the W8JK are simplicity and the fact that the pattern changes very little over very wide bandwidths. On the down side are the bidirectionality and, particularly when spacing is close, a low feedpoint resistance and rapid change in feedpoint impedance with frequency. The feedpoint resistance can be low enough that wire loss becomes a concern, and if not, matching network and perhaps even feedline loss can become significant. You're almost certain to be

running a very high SWR on the feedline, so very low loss line is a must.

Roy Lewallen, W7EL

the feedline wasn't an active part of the antenna, was the measurement
made over an ionospheric path, was the A/B comparison made at
>different times when other things may have changed?

The A/B testing is instant. All comparisons were done in the
usual up/down NVIS envionment. Mostly close in stations, and the
noise floor as another opinion. Just comparing any difference
in noise floor is a fairly accurate indication of efficiency in a
case like that. I didn't worry about the feedline being part
of the antenna, as I never would in the real world. I'm
running ladder line the whole way from the tuner to the antenna.
If the line is radiating, there would not be too much to do about
it at that point, without going to further measures. . I noticed
no obvious problems in tuning, or a "hot" line, rig, etc..

>What would be your confidence limits on such a experiment?

Very high overall.

>If you recorded your results, the variance would be revealing.

No. Not that time. It was just for my personal amusement.
In fact, I was out camping when I did that test.

>I suggest that the noise in your experiment would probably swamp the
true difference between your A and B configuration, and therefore your
>conclusion might not be sound.

What noise? I'm just using a switch to compare both antennas.
In that particular case, when switching to the coax fed, the noise
floor rose a bit, and strong signals that were way over S 9 rose
about 5 db worth on that particular meter. Easily repeatable
over and over. I'm not giving any numerical value to this
increase, I just know the coax fed system was the most
efficient. All signals increased when using coax. Noise floor,
desired signals, the whole deal. Switching to the tuner/LL fed
was like adding a small bit of attenuation. The way I see it,
the loss had to be at the tuner. And I was very careful in
tuning, using the least inductance to get a usable match.

>Your observation is (as you note) different to "on paper"
expectations, that might be reason to re examine the experimental
>setup in search of an explanation.

Why is it different? Actually, I found about what I was expecting.
I was expecting the coax fed to win. And it did.
Now, I realize this is a fairly sloppy test, and could be
improved greatly for accuracy, but there was no doubt
which system was better at that particular time.
The "on paper" expectations of the ladder line winning
would depend greatly on the losses of the tuner involved.
Sure, ladder line on it's own is very low loss, but add a
tuner, and things can change quite a bit as far as
system loss.
Now, granted the difference is small in general, but
I could see it. And if I can see it on a meter, it's not as
small as it's oft cracked up to be, or I wouldn't be able to
see it.

~~~~~~

You can do a pretty good evaluation of a tuner's loss by putting your hand
on the cabinet after running a few minutes. Just imagine a 25, 50 or
whatever watt resistor in there dissipating the same heat.

One needs to calibrate one's hand, of course. :-)

> So, what about Radar then...
>
> First, There are two "kind" of RF radiation, non-ionizing and ionizing and
> effects emanating from very high voltage nearby different materials.

*** Perhaps a typo, but the ionizing type is not a kind of RF
radiation. Ionizing radiation is nuclear radiation. This radiation is able
to strip electrons (and other particles) from atoms. RF does not do this as
we use it. It is unfortunate that we use the term "radiation" for both
things. In any case, it is not part of the original question.

> Normally, non-ionising is to be more or less compared to sun light....

*** RF, Light is Electromagnetic radiation and produces, as far as we
know and can be proved, Heat.

> As long as you are not overheating, there should be no harmful effects on
> you. ...

*** Widely agreed, yet feared by many.

> Now, radar radiation ...sometimes with stupidly high power....

** Not to the people USING it.

> If you are standing near a RF radiating radar station, the average energy
is
> what heats you up ...

*** Regardless of where/how you receive RF power, it produces a heating effect. Standing in an open field, you are picking up RF from EVERY transmitter within ear-shot (so to speak) and you have RF currents in your body, but of course, the heat generated is infinitesimal. Tests have been done to measure the low, yet measurable actual heating of things such as the human face in the RF field of hand-held radio like power.

> Some frequencies are really bad
> for us because different parts of our bodies absorbs different amount of
> energy on different frequencies.

*** The effect is that of heating and the most prominant effect is the heating of the water content in things - us included. Water (H20) absorbs RF best around 900 MHz and again around 2500 MHz. There may be more frequencies, but these are the two used in microwave ovens (900 earlier and 2400 now - I believe). When it does absorbe it (as opposed to reflecting it, which it may do depending on how good the impedance match is) the water heats. The old (possibly urban myth) story is of the radar techs up at the old Dew Line Early warning radars would stand in fornt of the High power radar antennas to warm up when working outside. The standard joke is that they had small families after that...

> Let's take a party example... Many key fobs, alarm buttons for car locks
> etc, operates on 418MHz. It happens to be approximately where a normal
head
> are resonating... Try walking just about out of range for your alarm/lock
> button for your car, point the key fob against your head and press the
> unlock key, voila, in most cases, you increase the range of the key
fob....
> Dan / M0DFI

*** Mine is around 320 MHz. I seriously doubt that the head resonates there, or has much of a resonance to speak of at any frequency. This "range extending of the keyless remote" is easily duplicated by various placements of your other hand, arm and other parts of the body, near the remote. I play with it often walking across the parking lot to the car. It can be best explained considering that being conductive, the body can pick up RF from the fob and be an added part of the antenna in a quasi-parasitic-element manner. The "antenna" in the fob is, at best, an extremely poor one (not being anywhere near 1/4 or 1/2 a wavelength, nor being a loaded antenna that is matched to the transmitter) and any help it gets will frequently be observed as positive. This effect is very dependant on things like polarization of the auto's receive antenna (if there is one with a recognizable polarization), polarization of "you as an antenna", direction (as the transmit pattern will most certainly be directional as well as the receive pattern), and probably innumerable other complexities of the RF environment you happened to be immersed in.

Any kind of a conductor can be brought close to the fob and have a similar effect. I've done it with long screwdrivers and pieces of wire. Careful placement of a half wave wire can achieve astounding range....comparatively (to me, anyway, but then, there are those that say I am easily amused). Nerd that I am, it's fun to see how much range you actually can get...just

for the bleep of it. I should get a life at times. (:-) Please no agreement.

73, Steve, K,9.D'C;I

Oh yea...the origainsl Radar near the office question. Do a search on something like the Russian radar illumination of the American Embassy. I believe there are those that claim the Americans which the Russians were radiating with Radar got irritable or some such symptom(s).

443. Starting point for antenna design

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-12 00:39:01 UTC
From: David <webreply@orbitcoms.com>
Message-ID: <Fyhxf.213965$V7.122439@news-server.bigpond.net.au>
Source record: 65404

Can someone explain to me how a new antenna design is started. Do you take an initial standard design and then enter it into a modeling program and optimize it for the required parameters ?

Is there a suitable reference book that would explain this process. I am thinking about the Cebik antenna modeling book but think this may only cover how to model and change an existing design,would it cover how to come up with the initial design in the first place ?

Example: Say I want to design a 4 Element Yagi at 921 MHz using 6mm diameter elements.

Is there a standard formula that would be used to calculate initial lengths and distances between elements. Then you enter this design into say EZNEC and use the optimizer to tweak the design.

Thanks in advance

Regards

David

There's an mfj switch, MFJ-1700C, that handles six antennas on one
side, six transceivers on the other. Rated up to 30 mhz, so may or may
not be right for 2 meters.

It would take hours to really answer your question fully, but I think I can help:

For most hams, when the flux gets above 100, things are picking up. Above 125, you'll hear comments about how great the bands are. Above 150, you can do DXCC in a week running QRP. Above 175, you'll ask the wife to call in sick for you so you can chase DX. Above 200, you won't have to call in sick anymore because you quit your job.

How's that? :-)

You need a transfer switch. Transco makes model 310 if you can find
one. They're usually priced like the high quality stuff they are tho.

448. Rax bassett and Savoy Electronics

Newsgroup: rec.radio.amateur.antenna

Does anyone in South Florida know what happened to Rex Bassett and or Savoy Electronics of Ft. Lauderdale?

Rex was making big antennas before WW II plus had a line of big (mainly commercial) transmitters).

In the 1950's Rex did some pioneer work on mobile antenna coils filled with helium. Later he sold Bassett
80 to 10 antennas (coils filled Helium) thru Savoy Electronics. He wrote for CQ and advertised in CQ and QST.

I suspect Rex has long since passed away but can someone clue me in on his history?

Have to agree, bought some really high dollar Scotch for New Years Eve in
1954 while in Japan. Flavor wasn't the same but it was as smooth as
chocolate milk. I was asleep before midnight. Had to quit that sort of thing
though, my Dad was alcoholic and I figured I'd probably inherited the gene.

>
> How's that? :-)
>
> Bill, W6WRT

Now, Add in the K and A indicators and the issues gets complex. In non technical terms the K and A averages subtract from the 'goodness' of the flux. Low K, 1 through 3, indicate good propagation. High K, 5+, indicate poor propagation good for taking a nap..

A values below 4 are good, 5 to 10 fair, 11+ are take a nap. Now if the A index hits 20+ take a long nap.

Seriously, Flux above 150 suggests very good propagation when K and A are low. Flux below 100 and high K and A suggests propagation is poor.

Hi Bob,

If there's any its on the order of 1:3. However, there's no point going there with any high expectations - or even low expectations. Going from a whip, or internal antenna to the external antenna you have your mind set on is a leap in improvement. The next leap of improvement will require $500 to a grand to set up a tower - and then start thinking about the antenna on it. All steps between leaps are small steps indeed.

You might try looking into phased arrays, but you should really concentrate on making one good antenna and noting your baseline in performance. On marker is how much noise do you live in? SWL varies considerably through the bands, through the day/night, through the seasons, and through the sun spot cycle. You have to consider that what you may be trying to hear just isn't hearable because of those same variables, much less an antenna.

I disagree.

I'd venture to guess that the average output power of a 100 watt PEP sideband rig is no more than about 10 watts unless heavy compression is being used. And I think you'll find that a 10 watt resistor inside a typical tuner cabinet -- representing loss of all the transmitted power -- will make a barely noticeable difference in the cabinet temperature.

Add to that the fact that the thermal time constant of the tuner is probably longer than the typical transmitting session, so the power needs to be averaged over the receiving periods, too.

If you're running a kW, you're up to 100 watts or so during transmit only. But can you tell the difference with your "calibrated" hand between 1 dB loss in the tuner (25 watts), 3 dB loss in the tuner (50 watts), or 100% of the power lost in the tuner (100 watts)?

I'd love to see the results of a double-blind study where a measured tuner loss is compared with an estimate made using Bill's method. But I think the chances of that are about the same as finding a double-blind study of the audio quality enhancement of $1000 speaker cables.

A very good source of starting designs is _Yagi Antenna Design_ by James Lawson, W2PV, published by the ARRL. It clearly illustrates the various tradeoffs which can be made in Yagi design, and gives lots of alternatives. There is no "ideal" design, since there are so many tradeoffs to be made -- gain, front/back ratio, bandwidth, size, which you can't maximize all at once.

EZNEC doesn't have an optimizer -- if you use EZNEC you have to tweak the design yourself. People who have used optimizing programs have told me they've often been able to improve on the "optimized" design by hand tweaking with EZNEC.

That's just it for me. I don't want to run the risk, and after seeing what it did to friends and relatives as well, it made up my mind in high school. Tried it. It tasted AWFUL no matter what, so I prefer a Coke. Oh, if someone insists I take a sip with him, I will. But since I simply do not like the taste of alcoholic drinks, I simply drink enough to satisfy the buyer and let it go. I just don't like it the same way some people don't like broccoli or cauliflower and I never will. :)

Steve,

Your assertion is simply not correct. You may be thinking of particle radiation, such as electron (beta), neutron, proton, alpha, cosmic, etc., but pure photon radiation can certainly be "ionizing". A well-known example is ordinary medical x-rays. Ionizing photons would not typically be called "RF", but there is no difference other than the energy levels.

(I spent so much time in the early stages of my career dealing with intense sources of ionizing radiation (photons) that I still glow in the dark.)

Back to the original question, ordinary radar is clearly not "ionizing". Not a good idea to be too close, due to possible thermal effects, but otherwise no big deal.

Between 25, 50 and 100? You betcha, although calibration of hand might have
to be checked.
Remember, we're not talking NIST here, just an idea of what's happening.

Roy, I did some experiments a few years back when the FCC OET formed a view that the average power of an SSB voice signal was something like 40% of PEP. My experiment was to modulate a TS440 normally with ALC, with and without compression, and to analyse the audio captured from a comms monitor. The ratios averaged over 30s that I obtained were -13dB and -11dB. Those numbers are consistent with the practice in carrier telephone systems in estimating the power of a n channel multiplex.

Later, I have made the same measurements off-air with FSM which reports measurements with an average responding detector, RMS detector, quasi peak detector and peak detector. The results averaged over seconds were -10 to -15dB. I have no idea where OET got -4dB (averaged over 6 minutes).

I don't doubt that it is possible to get several dB loss in an ATU, but it says more about the understanding of the person using it in that way than the basis for a law for tuner loss.

A chap was telling me on air a few weeks back how good his MFJ tuner was, it could tune anything. He got 1:1 and discovered he didn't even have the aerial connected, how good is that! I suggested he take the covers off and see if the coil support strips had softened / deformed / charred. How could I tell him to stop viewing the world through an SWR meter?

Jimbo

How much power?? I have built some fairly good coax switches for 144
MHz with microswitches. They wont stand up to a KW. But they sure can
work OK at 10 or 20 watts.

I'd consider using three spdt coax switches for your application.

There are many parameters to chose in designing an antenna. Beyond the antenna itself are the costs, tolerable size, available materials and available tools.
I recently took the ARRL antenna course and purchased Roy's EZNEC+ program. I describe my current level as an "advanced beginner".

I once scaled a 4 (5?) element yagi for an antenna measuring event from the Arrl Handbook to 1296mhz using a piece of plastic tube for a boom and #12 wire for elements. The measured gain and the plot looked pretty much like the book said it would. It fits in a "book-sized" box.

My current project is "What can I do with a 20 foot radiator?" Working out the details (the devil is indeed in the details!) sure is a lot easier with EZNEC than it is with physical modeling.

There are not many antennas that cannot be evolved from a straight piece of wire.

Assuming a 20 ft. vertical with 20 ft. radials, how about
feeding it with an autotuner, like the SGC-230, and using
it for 40m-10m? It will also work at reduced power output
on 75m.

I second Roy's recommendation and add one. If Yagi antennas are the
interest then in addition to Lawson, you need Leeson; "Physical Design
of Yagi Antennas", by David Leeson, W6QHS.

It is not enough to come up with a super-duper electrical design if
you can't actually assemble it or keep it in the air after it's
assembled.

For example many "optimized" or "fifty-ohm feedpoint" designs are so
mechanically unbalanced that they put a large unbalanced strain on the
rotator if mounted near the boom center. If mounted at a static
balance point they turn into a windcock and damage the rotor from that
stress.

So a well engineered antenna is one that not only performs well from a
gain, FB and SWR standpoint, but is also easy on the tower and rotator
and will last years in the air without degradation.

If he builds it with aluminum and uses the correct
grade, should be no problem.

Since his tower tapers, he could use larger
wheels at the top of the device to keep him
plumb at the higher levels.

Have you looked into renting a bucket lift,
not too expensive for one time and a lot safer !

Source record: 65284

There are some other advantages to the 8JK antenna that are not so obvious:

1. You don't need to worry about whether a DX station is coming in via long or short path, since you get them both at once, and the strongest one wins.

2. You can investigate propagation to various parts of world by listening for your own round-the-world echo in various directions.

I was a colleague of John Kraus W8JK for many years, and he used to tell me about his round-the-world experiments. I was in his shack once when he did it. Of course you need rapid switching to go from transmit to receive. Typically a single dit is used.

I have a 2.4 Ghz transceiver circuit that is used in a mobile wireless application. The application runs from a watch battery so power is crucial. The device will only need to transmit up to 4 or 5 meters to its receiver. I need to know what kind of antenna to use. I read that a dipole is typical. My question are:

1 - what is the minimum length that this antenna can be?
2 - what is the minimum diameter that the antenna can be?
3 - can the antenna be etched on one side of a PCB (to avoid attaching a physical cable)?
4 - does the length / diameter of the antenna affect the power output?
5 - any manufacturers you know of that sell very small antennas for this application?

What I need is the smallest antenna possible!

Thank you for your insight.
Johann Blake

Look into low power Wi-Fi designs and you should find the right one for
your application.

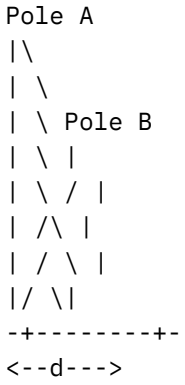
476. Brain Teaser

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-12 19:09:49 UTC
From: Cecil Moore <mycall@arrl.net>
Message-ID: <1Qxxf.8331$dW3.1056@newssvr21.news.prodigy.com>
Source record: 65287

Problem:
There's a rather strange antenna with two straight wire elements. The two elements are supported by two non-conductive poles, Pole A and Pole B of unequal lengths. The bottoms of the poles are at ground level and the ground is flat.

One straight 10 foot wire runs directly from the bottom of Pole A to the top of Pole B. One straight 20 foot wire runs directly from the bottom of Pole B to the top of Pole A. The feedpoint of this strange antenna is where the wires intersect and that point is exactly five feet above the ground. (The two wires form a non-symetrical 'X' between the poles and the center of the 'X' is exactly five feet above the ground.)

Question: What are the heights of Pole A and Pole B, and how far apart are the two poles?



P.S. None of my math students can solve this problem.

Source record: 65288

Hi Johann

There is no doubt a lot of info on internet articles you could wade.
through. Since you have a practical requirement though I'll try and answer.

The length and diameter of an antenna is related to the frequency. In
rough terms a half wave in free space on 2.4GHz is calculated as
300/2400MHz/2 metres or about 60mm. A half wave dipole antenna tends to
be shorter than this by a percentage between about 85% and 98%. The
variation being a function of the material diameter vs its length (ie
the fatter the antenna element the shorter its length) If you etch the
design into a PCB the dielectric around it (PCB insulative material)
will lower that percentage more. I don't know how much off hand.

Within limits however you can match any transmitter to any simple
antenna length. Small variations and errors in length (say 20%) wont
deter very much from the performance provided you have done a good job
coupling the transmitter to it. If however you use a simple element of
more than a half wavelength you can get an undesirable pattern of
radiation from it. Gain antennas like yagi's will suffer badly from this
much variation though.

Coupling/tuning in this sense means getting a maximum power transfer
from the transmitter to the antenna.

Antennas for longer distances on 2.4GHz are almost always devices built
for gain. They can use a cluster of dipoles phased to concentrate the
radiation into a narrower pattern, hence the received signal at the
other end is stronger than from a simple dipole. The downside is of
course if either end is moving/rotating in respect to the other. Loss of
signal results. (Think of a searchlight)

Yes etching an antenna on a PCB is a good way to do it. "Patch antennas"
might be the term to look for, as well as "slot antennas" with PCB as
part of the search criteria.

One of the conditions you didn't specify is whether the ends of the link
are fixed or moving. If they are fixed you can get away with lower power
and gain antennas. If they are moving you probably want an antenna that
radiates equally in all directions. This is actually difficult to do as
there is always variation in different angles from the antenna. A dipole
for instance radiates best at 90 degrees to the element. There is
however virtually no radiation directly off the ends. This doesn't make
the system unusable though. Some of the signal will get through via
reflection off other objects and a very useful amount will come off at
(say) 10% from off the ends. If you have enough power margin it will

still work. It will be something like (say) 5m range at almost any attitude and 50m range if you hold the antenna just right!

Smallest antenna? A slot would be maybe 60mm long and 20mm wide if etched to a PCB. A quad type element etched on a PCB may me 30mm x 30mm. You could also make a 1/4 wave groundplane. That's a 30mm or so wire perpendicular to a ground plane area (eg PCB) a minimum of 60mm diameter. If you can suffer some efficiency loss you can etch a loaded dipole pattern on a PCB maybe 15 x 10mm but it would be a good idea to test whether the distance loss will be okay in your environment.

If you hand make the antenna the coax etc attachment becomes a large lumped reactance/resistive load that has to be allowed for when adjusting for best coupling. Likewise a etched PCB antenna will be affected by components mounted on the reverse side as well as the (say) plastic etc box it is mounted in. The rule is to tune it with everything attached.

For the purists out there I have watered this down some and tried to keep heavy theory out of it. I hope however you'll still find it useful.

Cheers Bob W5/VK2YQA

Don't remember where I saw it (about 30 years ago), but there was a parallel
resistor problem that was solved similar to this.

I've had no trouble coming up with two equations and two
unknowns but have had a heck of a time trying to solve
those two equations. I've solved it graphically and by
itteration, but an algebraic solution has so far escaped
me. An algebraic solution is what I would appreciate.
After awhile, I'll post the two equations with two unknowns.

> --
> 73, Cecil http://www.qsl.net/w5dxp

i get it down to an ugly 4th order poly that i just don't feel like trying
to solve tonight. the way i went was:

two pythagorean equations (where G=separation distance along the ground)
A^2+G^2=20^2
B^2+G^2=10^2
subtract these two to get
A^2-B^2=300
solve for A
A=sqrt(B^2+300)

then use similar triangles to get two equations like:

(A-5)/g1=A/G
(B-5)/g2=B/G
where g1+g2=G and g1 is the horizontal distance from pole A to the feed
point and g2 is the horizontal distance from pole B to the feedpoint.
sort them out to get
g1=G(A-5)/A
g2=G(B-5)/B
add them to get
g1+g2=G(A-5)/A + G(B-5)/B
and since g1+g2=G
G=G(A-5)/A + G(B-5)/B
cancel a G, expand, contract, collect... etc to get
5/A+5/B=1
substitute the sqrt(B^2+300) for A and do a bunch of expansion and
collecting
to get
B^4-10B^3+300B^2-3000B+7500=0

which numerically gives a B about 6.85 giving A about 18.6 and then go back to the beginning and solve one of the pythagorean formulas for G to get about 7.3.

there may be a simpler substitution using a bunch of similar triangles and getting it down to 3 equations, but i think you will always end up with a 4th order equation to solve. even doing it graphically is ugly.

Bob Bob wrote:
"In rough terms a half wave in free space on 2.4 GHz is calculated as 300/2400 MHz/2 metres or about 60 mm."

I agree with Bob Bob.

A quad antenna has a smaller maximum dimension then 1/2-wave. Its circumference is a full wave, but that is divided by pi to calculate its diameter. The configuration is not very important. It can be circular, triangular, square or a figure with almost any number of sides. Performance depends on the area enclosed by the figure. If square, it has 1/4-wave sides. The diagonal is 1.414 times the length of a side. In the case of a square quad for 2400 MHz, the sides are are about 1.25 inches long.

A quad with a circumference of 5 inches may seem small but it is not a "small loop" which couples to the rest of the world via the plane of the loop. The quad couples to the rest of the world broadside to itself. Kraus gives the radiation resistance of a full-wave loop in Figure 7-10 on page 209 of his 3rd edition of "Antennas" as just over 100 ohms.

Best regards, Richard Harrison, KB5WZI

Yep, that's what I came up with also but I don't remember
how to solve it. There's only one real-world solution. I
wonder if two of those solutions are imaginary and one
negative?

> which numerically gives a B about 6.85 giving A about 18.6 and then go back

I worked them out to a little more accuracy than that but
those are correct values within your accuracy. My solution
is at work and I'm at home but I remember the distance
between poles is 7.299 ft.

I also came up with two simultaneous equations involving
trig functions of angles but couldn't solve them either.
It looks like a simple problem but looks can be deceiving.

Source record: 65295

As Roy has said many times, what counts is the gain in the desired direction
and angle above the horizon. A three-wire, terminated, well-designed
rhombic can have a lot of such gain. However, while its impedance bandwidth
(frequency range over which the input impedance does not significantly
change) will be huge, a pattern bandwidth of perhaps 3:1 is about all that
can be attained. In other words, the pattern degrades, as frequency is
increased, to an unacceptable degree long before the input impedance
degrades.

On the other hand, to be able to work VU4 from the upper Midwest might
require a large and tall rhombic.

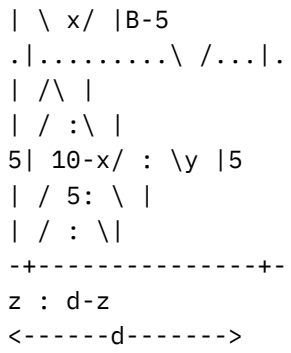
I think you can solve this by constructing equations based strictly on
Pythagoras.
(Enlarging your drawing to label some more sections)

```
Pole A
|\
| \
| \
| \
| \
| \20-y
A-5| \ Pole B
| \ |
```



| \ x/ |B-5
.|.....\ /...|.
| /\ |
| / :\ |
5| 10-x/ : \y |5
| / 5: \ |
| / : \|
-+---------------+-
z : d-z
<------d------->
Here I have broken side A into sections 5 and 5A-5,
B into 5 and B-5,
20 into y and 20-y
10 into x and 10-x,
and d into z and d-z

Nor for some right triangles, a la Pythagoras.
We have 6 unknowns (A,B,d, x,y,z), so we need 6 triangles to t
completely solve the system.

First the original triangles:

A^2 + d^2 = 20^2
B^2 + d^2 = 10^2

Then some using the smaller, inside triangles:

5^2 + z^2 = (10-x)^2
5^2 + (d-z)^2 = y^2
(A-5)^2 + z^2 = (20-y)^2
(B-5)^2 + (d-z)^2 = x^2

Shall I bore you with the process of wading through the solution of
this set?

Nah...

A = 18.6202
B = 6.8345
d = 7.3000

I got a little help from Mathcad. ;-)

Hi,

Some probably dumb questions, but am a bit of a beginner with all of this.

Will be putting up an otside sloper or inverted L.

Receiving only.

a. If I run the antenna wire thru a closed metal loop for fastening
purposes, do I run into any effets from having a
"shorted turn" over the active antenna wire (receiving only) ?

b. Any problem if I coil up a bit of the excess wire, perhaps a foot or
two, into a 6" loop at the end ?
Guess I'm asking about it becoming an added inductor due to the coil.

Thanks,
B.

You miss my motives!
I have a Cushcraft A4 beam that works very well with my Ten Tec
Pegasus transceiver (inboard LDG tuner). In my eyes it is the perfect
rig!

I am not breaking any new ground. I am simply doing the lab exercise
of validating the EZNEC calculations. I may find it worthwhile to drop
to an 8-foot radiator and higher (10-Meters?) for ease of
construction. The principal area of interest is in radiators less than
1/4 wave in length.

At the moment, I am especially interested in the different feed
arrangements. I am starting with the "Gotham" style of a single base
loading coil and minimal radials then I plan on an autotransformer
arrangement. I have a fair amount of room, a lot of scrap metal and
wire is cheap! The principal limitations are time and my level of
intellect...

Staying on track will be a problem, moving the load up the radiator is
already looking appealing!

Hi Bob,

Some. By the degree of the metal's resistance. It would take a very
serious degree to be noticeable. Hence Doc's suggestion of probably
"No" stands.

>b. Any problem if I coil up a bit of the excess wire, perhaps a foot or
>two, into a 6" loop at the end ?

Also called a choke. It can help at some frequencies and impede at
others (too many details left unsaid by you). Again, from what you do
say, probably "No" still stands.

So how would you put these two equations in a matrix?

2*sin(B) = sin(A)/[2*sin(A)-1]

2*cos(B) = cos(A)

Good point, obviously not linear algebra since you cannot separate the variables. The only way I can see to handle such a problem is successive substitution.

I think you are right the problem might be solved easily with geometry
by breaking up the problem using similar triangles. The product of the
triangles on one side being equal to the other side. No trig needed.
However, I haven't actually tried to solve it.

>
> Thanks,
> B.

hello B

answers depend on are you using insulated or uninsulated wire
if using uninsulated wire you will want a insulator between the wire
and the "closed metal loop for fastening"
coiled up excess wire is no real prob excpt
if its uninsulated and the turns rub each other
just cut off the excess wire
if its insulated wire don't worry

wire hf receive antennas like a sloper or inverted L are very
forgiving
realy can play around with it and not degrade how well it will receive
for most wire antennas, I use THHN # 14 gage stranded insulated house
wire
sells cheap at home owners hell
wire antennas for receive are fun to play with
don't worry
just stay away from the power lines and you will be ok

yours truly Mac w8znx

There are grounds and there are are grounds.

Lightning ground
House wiring safety ground
Antenna counterpoise (ground)
Ham shack common RF bus ground

If you live in an apartment building or if you use soundcard modes you
will soon find out that using the building's electrical safety ground
as your antenna's counterpoise is a bad thing.

Dont try to use an endfed wire antenna in an apartment.
You will be unhappy if you try to use your TV and soundcard speakers as
your antenna counterpoise.

I came to the conclusion that balanced antennas are the answer.

Put up a dipole or, better yet, a loop antenna.
Balanced antennas have their "ground" as part of the antenna itself.

I personally have never used a balun at the antenna but have used
choke baluns near the rig and have used 4:1 baluns at the tuner.
I often use an antenna tuner and ladder line so am not so sure that a
balun at the antenna is a good thing under those conditions.

I have experimented with "artificial grounds"
They are just a series L-C circuit that you insert between your
station common RF bus and your counterpoise system.
Series LC circuits act like a short when tuned so the idea is that
when your station counterpoise system is tuned with the series
LC circuit, your station bussbar ground will have the highest current
path to counterpoise system ground

You can make an RF current meter with a diode a toroid
a little magnet wire and a volt meter.

MFJ artificial grounds or tuned counterpoise tuners have you
tune for max current through the series LC circuit.

I have found that max current through the series LC circuit is not
always the best setting for getting minimum rf in the shack. I
use my soundcard speaker amp as my canary - tune the
counterpoise for least audio out of the speakers.

KL7R

PS, I live in a rain forest. I dont know a thing about lightning
grounds.

Nice try, but at least today's students are taught to read the entire
problem.

"Zero" separation is a solution for part of the problem, but it ignores
the requirement for an "X" configuration with the crossing at "exactly"
5 feet.

Perhaps you have a definition for the crossing point of two parallel
lines. I must have missed that one in my edumacation.

Beware of zero in math problems. It is really easy to prove that 1 = 2
and other such niceties.

>
> Will Mathcad solve simultaneous equations?

Yes, in several ways. My favorite is the iterative solver, whereyou specify and arbitrary number of equstions or other constraints and gesses for the solutions that you think are near the solutions you expect. This solver churns through a search and refinement algorithm till it comes as close as possible ot meeting your constriants.

There is also a single equation (root) solver that works on any equation you can put in the form of (expression)=0. There is also a matrix form of the solver in which you make a matrix of the equations, specify in a second equation, the variables you want solutions for, and those variables are solved for symbolically in terms of the other variables. You can also select a variable in an equation in only one variable (but not necessarily with the variable isolated on one side and all the math on the other) andfrom the symbolic menu, select solve variable. Sometimes this gets stumped or produces such a mess that it just puts all the arithmetic needed on the clipboard as a huge expression. If the equation contained several variables and you select symbolic variable solve, a symbolic expression in terms of all the other variables except the one selected that equals that variable is produced (again, unless you stump the computer).

I used this last method to work through the substitutions to get down to an equation in one vaiable, but that produced the clipboard full of arithmetic expressions, so I use the ierative solver to find the solution of that one equation in one unknown that produced a result near my guess (for the baseline, d, in my case, that was less than 10 but more than sqrt(10^2-5^2) to eliminate the negative and imaginary results).

"kl7r" wrote
> Dont try to use an endfed wire antenna in an apartment.

==========

If the domestic plumbing system, hot and cold pipes, central heating system and mains wiring are connected together, then the impedance to true ground, as a whole, will be very low. The RF potential difference between 'ground' and true ground at the lower HF frequencies will be small.

In principle it could be measured - IF you could find a real ground.

The actual distance in wavelengths between 'ground' and true ground, wherever that may be, is indeterminate and inconsequential.

In the extreme case the elevated ground system can be considered as a sort of Faraday cage with no more than normal interference between the electrical equipments in the vicinity.

By not using low-feedpoint-impedance anrtennas, such as exactly 1/4-wavelength or 3/4-wavelength in length, things can very often continue as normal. It is, in any case, undesirable to use very low impedance antennas even in good ground circumstances.

And antennas crudely 1/2-wavelength in length work just as well with either good or very poor ground systems.

Appartment and flat dwellers should not be discouraged from simple endfed antennas. In all probability they will be successful. Very often they are unable to erect anything else.

My own experience extends from successful working with end-fed wires from bedrooms to a 13th storey in an appartment block. The appartment block antenna was a 0.3 wavelength sloping wire on the 160m band, open circuit at the bottom end fed at the top.

Ground was an aligator-clip connection to the nearest hot water radiator pipe in the domestic central heating system. But I could just have well used the cold water pipe to the flush-tank in the toilet had it been nearer.

Appartment dwellers - carry on as normal!

Reg, G4FGQ.

technically that solution doesn't work since the intersection height of the
two wires can't be solved for if there is no separation between the poles.

The trouble with pure maths programs is worrying about whether the answer is the right one from amongst the great variety of other possible "equally correct" answers.

For confidence in results, it is necessary to know EXACTLY how a program deals with the problem it is presented with. Generally this is unknown. Users are seldom mathematicians. Otherwise they would not be using the program.

i used the polyroots function in mathcad and it comes up with 4 roots. two are imaginary and one is less than 5 which is impossible... if you shifted coordinates to the 5' high crossing level and calculate from there the equation is a bit simpler i think and the impossible root would come out negative. the one that fits gives:
A=18.621
B=6.835
G=7.299

Hello Everyone,

There's one thing I need to know for the purpose of my simulation
- that is the order of magnitude for currents/voltages inducted
in the antenna, or, to be more precise - answer for the question below:
can termination of the transmission line be simulated in Spice as
voltage generator (VSIN) with 75 Ohm internal impedance and particular
frequency AND amplitude ? What amplitude could it be ?

Best Regards,
Peter

Are you simulating a receiving antenna or parasitic elements?
The main wave in an ordinary transmitting dipole is conducted,
not inducted.

Question:
What is the real world effect on this antenna's performance if the
dimensions are calculated to the nearest inch?

Suggestion:
Use a rough graphical solution to come close to the ideal dimensions. Erect
the antenna and then make minor changes in conductor/feed-point dimensions
to minimize VSWR and maximize efficiency.

Peter wrote:
"What amplitude can it be?"

A receiving antenna has a radiation resistance. The load which extracts most power is a conjugate match for the antenna. With radiation resistance perfectly matched to receiver input resistance, the radiation resistance becomes the Thevenin equivalent source resistance feeding an identical receiver input resistance. 1/2 the voltage induced into the receiving antenna is used to re-radiate energy received by the antenna. The other 1/2 appears across the receiver`s input resistance.

For a professional explanation of this topic, see Kraus` 3rd edition of "Antennas" page 32. "All about antennas at a glance".

Actually, it's a classical mathematics problem involving ladders.
Since Kurt N. Sterba uses ladders for antennas, it occurred to
me too post the problem as an antenna problem.

==========

I first heard of the problem about 50 years back. It involved ladders in a passage-way leaning on two enclosing brick walls.

The solution involved a pair of simultaneous equations and Pythagorus' "sum of the squares on the hypotenuse, etc."

Pythagorus would have had little difficulty with it. He probably cribbed his ideas from the ancient Egyptians who built the perfect triangular pyramids using only copper tools several thousand years before.

We can do nothing but admire the ancient peoples who lifted themselves up with their own boot-straps. The Greeks, Egyptians, Babylonians, Sumerians, Persians, the peoples of North and South India, and, not the least, the Chinese.

Their descendents can teach us ill-educated westerners a lot. Instead of using guided weapons and threats of much worse, perhaps we should listen and take careful note.

The first essential is to get rid of Bush and his puppy-dog Blair.
Then severely regulate the oil, gas and energy corporations.

Reg.

something tells me you missed the point... this is not a real antenna, it is purely a math puzzle and not something anyone would really want to build.

on the other hand, the accuracy needed for cutting wires or aluminum for antennas depends on the frequency and antenna design. some designs are rather forgiving, others very critical. and on 160m where you can be a foot or two off and not notice much change you want to be much more accurate on 70cm and you adjust microwave stuff down to small fractions of an inch.

Hey guys, I don' t have a design ready to post yet, but my question is.. How high should my tower be for my vertical sector wifi antenna? I'm currently still undecided on which antenna to get, but my radio is gonna be a 400mw mini-pci nic and the antenna is going to be a 17-24db vertical sector antenna. I'm looking to cover distances of 4-15miles.

What you see is what you cover

> I'm currently still undecided on which antenna to get

It depends on lot of factors. As a (over) simplistic method use LoS
equation, add some margin for fading and calculate link balance to get
ERP figures. From ERP you can find out the antenna you need for your
feeder losses.

Generally speaking you should have an unobstructed line of site to the other end of the link. Think of WiFi as being a light beam.

Work out the path loss based on the basic distance formula and plug your power, losses and RX sensitivity in to determine your margin and thus max range. Radiomobile and/or UKWtools can be used for this and some allowance for terrain as well.

Hi OM,

It, or any link, only sucks as a function of what is called multipath.
This means that reflections combine at the receiver to blur the
signal. For conventional modes this is at worst obnoxious. For
digital it can mean total bit loss. In all practicality it translates
to high BER (bit error rate) and low information bandwidth due to
repeated packets being needed. The solution is not more power because
the problem will still be the same, only louder (so to speak).

Instead, the receiver antenna should have the gain so as to exclude
the signals coming from other directions. This exclusion is a
property of antenna gain, it is like cupping your ear to hear better,
there is not more signal to be had, you are merely excluding
distractions and focusing what is available.

400 mW in the clear and visible to a receiver is more than enough.
Your second problem is that you may not have 400 mW at the end of the
transmission line, at the antenna, because of the enormous loss in the
line if it is very long. That has already been discussed by Bobï¿½.

In addition to Richards comments

As a guide I use to run two spread spectrum links. One on 2.4GHz over about 10km and another on 5.6Ghz over 8km.

The 5.6GHz link was one of those Cisco patch panel things with 30dBm EIRP. The RF power was about 8dBm. We had 56MB/sec about 90% of the time. (Including the BER) (keeping in mind that this is aggregate)

The 2.4GHz link was initially setup wrongly. There is a parameter one has to set that defines the max distance of the link I think to reduce packet retries and collisions. When it wasnt set the rate was a real bad and flakey 1MB/sec but when fixed 11Mb/sec was good about 80% of the time (incl BER)

What eventually killed the 2.4GHz link was mainly other users on the same freq. The radio design didnt seem to allow it to hop away from interfering signals. A cold power boot often resolved the issue as it chose another clearer freq. We eventually dropped it to 2MB/sec with about 50% reliability. We didnt really have any major multipath problems that were noted in the design phase. We did however have a building go up in the path and for a while were firing between two concrete floors! (We moved one end later)

We used a 2 metre gridpack horiz polarization at each end (to avoid some user interference). One end had a 16m run of LMR400, the other about a 12m run. I dont remember the calcs/margin we did off hand, sorry. We didnt however exceed the 30dBm EIRP legal limit. (The company had a very good standing with the ACA/ACMA so we were kind of pedantic about doing it right)

Both links were kind of high point to high point accross Sydney. ie There was a large series of valleys between each site.

Hope you find this helpful

Cheers Bob

No, it only takes microwatts at the receiver to do the job. Start at
the receiver, not the transmitter. Ham radios with only a Watt or two
talk to the Space Shuttle (hundreds of miles) without too much
trouble.

So what is it you would say determines wither or not my signal will be received on the other end? I mean with just a regular soho wifi access point in open space you can only communicate within a couple hundred feet (That's open space). If gain/wattage isn't so important when we're talking distance.. what is? Line of site? Are you saying that that I can shoot my 30mw signal from my soho access point couple of miles?

Ah!

Only 30 mW? So you were expecting the antenna to boost it to 400
without any loss of the 30 getting to the antenna?

Why it seems limited is in exactly the problem described as multipath.
All those echoes are roughly the same strength because you are sitting
down low near many reflecting surfaces. "Open space," is not always
so open unless you are sitting in a pasture. Simply because there are
no obstructions between you and your destination does not mean the
signal is not traveling by many, many different paths - in fact, it is
guaranteed.

As I said, this is more a receive problem.

I've spoken with a guy who has set up a number of reliable point-to-point links in the Sacramento valley, using standard unamplified off-the-shelf SOHO-type access points and/or PCI cards or USB dongles. He said he achieves reliable performance, with a good margin of signal strength to handle rain fade, etc., with no amplifiers, over distances of as much as 5 miles.

The key to doing this are a clear line of sight, an antenna with high directional gain at each end of the link, and careful aiming. Getting the radio right up at the antenna (rather than at the end of a length of coax) is also beneficial.

The carefully-aimed highly-directional antennas give you several advantages, over a standard SOHO omni antennas. The directionality increases the effective radiated power of the transmitter (50 milliwatts through a 20 dBi antenna is equivalent to 5 watts isotropic), it increases the receiver's effective sensitivity by the same degree, and it makes the receiver _less_ sensitive to interference arriving from other angles (e.g. competing transmitters).

Also, with proper choice of antenna, you can select the signal's polarization angle. Since most home and business access points seem to use vertically-oriented antennas (and thus a vertically polarized signal) you can reduce interference problems by using point-to-point antennas which are horizontally polarized.

The guy I spoke with was not complementary about the idea of trying to "blast" signals through by using high-power transmitters or amplifiers, and blanketing a large area with the signal.

You can buy wire-dish parabolic antennas for the 2.4-gig ISM radio band quite easily. I think I've seen 'em advertised as having 15 to 19 dBi of gain. One of these at each end of the link would be a good place to start.

You seem to be getting too much information and not answers to your questions.

400 milliwatts is plenty of power. The performance of your system will be governed by two simple factors: how high are the antennas; and, how sensitive is the receiver?

For ten miles your antenna height above average ground should be close to 100 feet. For seventeen miles you need an antenna height of close to 300 feet. I suspect both heights are excessive for your application. Also, the cables connecting your transmitter to the antenna have losses. So, mounting the transmitter at the top of the antenna would be preferred. An alternative to the 100 foot antenna would be 70 feet antennas, one at the transmitter and one at the receiver.

Receiver sensitivity is unknown. I regularly communicate 20+ miles with 500 milliwatts from a ham radio walkie talkie. [the receiver is located on top of a mountain] Most communiation grade radios can receive a signal as small as 0.000000000000002 watts. [one millionth of a volt]. So, you can see why I say 400 milliwatts is plenty. So, the receiver you use should have a moderately good sensitivity 5 microvolts or smaller.

Over relatively flat terrain, with very modest antenna [20 feet high] a four mile circuit should be possible. Longer paths will require spending $$$.

It's important to point out that using these extreme high gain antennas
with out a license is illegal in the U.S. The guy that invented the
"pringles can" antenna was an FBI agent so he was not prosecuted, but
if he had been an average citizen the FCC would have come after him.

Then the question becomes which if any of the 14 WiFi channels is
actually in the 2.4gHz ham band.

Here in Israel it's even worse. WiFi and terrestrial 2.4gHz ham activity
is limited to 100mw EIRP. If you use a gain antenna, you must reduce
the transmitter power proportionaly.

Thank you so much Amos! I was aiming for a 40feet-ish tower. Tripod base with an adjustable inner tubing which is where the antenna will be placed on at the top. So basically I was thinking 20ft tall tripod with cup-like guides allowing me to adjust the inner 30foot long inner tubing/pole up to 20feet on top of the tripod giving a total high of 40ft(10feet of the inner pole will sit inside the tripod). I'm currently in the process of drawing up a diagram to show a local metal welder, but that's my basic idea right now.

Hi Tek

Your ambition impresses me. 40 feet seems awful high unless those
support legs are anchored well.
I have a little WiFi site that uses surplus satellite TV dishes with
BiQuad illuminators. I have chosen to locate the Access Point at the
transmitting antenna in an effort to minimize the loss to the coax to the
computer. I have a Bridge at the receiving computer end. CAT-5 cable
takes the signals to the computers.

Jerry

Hi Amos

From memory the Cisco 5.6GHz box had a path prediction sensitivy number of about -87dBm. ie full speed with that input to the RX. I suspect that at a lower data rates and extra 10dB might be a good number to use. I have seen that larger microwave system manufacturers do publish their specs so look it up for the equipment that is going to be used.

FM rcvs on 2M can often go to about -117dBm. An SSB rcvr on 2m with a preamp hits thermal noise at about -141dBm. This also needs a good human ear.

Cheers Bob VK2YQA

Well I plan to have a 5-6' squared concrete slab inwhich the tripod legs will be bolted down to. The access point will sit in a outdoor enclosure prolly 2-3feet away from the antenna on the pole. The inner tubing will come down for easy access making the total height of the tower 30ft. There's just soo much variables involved that determine if this thing works properly.. so I'm planning to overshoot in hopes that I will get it just right.

Here's the access point :
http://www.wisp-router.com/product_info.php?products_id=450&osCsid=ded957eab06d3d213602459103e1168b

And the radio:
http://www.wisp-router.com/product_info.php?products_id=399

Plan to use a based OS on this setup.

Not strictly true, although your point is well taken.

It's true that WiFi equipment must be tested and certificated as a
system. Using an off-the-shelf gain antenna, cabled to an
off-the-shelf WiFi AP/card, will almost certainly void the
certification, and then using the device becomes technically illegal
under Part 15, and unless you have a license for another service which
allows it (e.g. Part 97 ham license) you could be cited for it.

There are commercial WiFi radios whose manufacturers have tested and
certificated them with such high-gain antenna systems, specifically
for point-to-point connections. If you buy one of their radios and
one of their antennas, you can use 'em within the Part 15 rules, and
you'll be fully legal.

It's not so much the antenna itself... it's the certification status
of the antenna/radio system, as well as the EIRP.

>Then the question becomes which if any of the 14 WiFi channels is
>actually in the 2.4gHz ham band.

Check the ARRL's "multi-media wireless" interest group pages for
details on this. My recollection is that there are one or two 802.11b
channels whose power spectra fall within the ham-band 2.4-gig
allocation and also fall outside of the ham 2.4-gig "weak signal"
bandplan segments.

>Here in Israel it's even worse. WiFi and terrestrial 2.4gHz ham activity
>is limited to 100mw EIRP. If you use a gain antenna, you must reduce
>the transmitter power proportionaly.

There's a similar proviso here in the U.S., but for point-to-point links it's not as severe as that. If I recall properly, for a point-to-point link, once you exceed 1 watt EIRP, you have to subtract one dB of transmitter power for each additional 3 dB of antenna gain you throw into the equation.

Techmanx wrote:
"How high should my tower be for my vertical sector with antenna?"

Assuming line-of-sight is needed, the distance in miles to the horizon over smooth earth is: the square root of twice the antenna slevation in feet. You may want to add to the calculated height to allow first Fresnel zone clearance at the path grazing point.

Best regards, Richard Harrison, KB5WZI

Bob Bob wrote:
"Work out the path loss based on the basic distance formula and plug in your power losses, and RX sensitivity to determine your margin and max range."

Add in the antenna gains. You`ll need them to offset path and transmission losses.

Margins involve choices. Performance and reliability depend on those choices. I often choose to imagine the earth with only 2/3 its actual diameter for my path profile. Then I use 0.6 of the first Fresnel zone for added clearance at the path grazing point. You need 30 or 40 dB excess signal into the receiver under normal conditions to make the receiver very quiet and to allow margin for path fades if you need high performance and freedom from fades.

Path loss is computed from frequency squared times distance squared with constants as needed for the system you are working with. Someone has usually worked up a chart of path loss versus distance for the frequency you are working with. Every time distance doubles, loss increases about 6 dB.

Best regards, Richard Harrison. KB5WZI

Telemax wrote:
"And would you guys say my 400 mw radio is overkill for 4 - 10 mile shot?"

Depends on the whole system. The gains and losses must be totalled to check for satisfaction.

Industrial microwave I put in almost 50 years ago was limited by the klystrons available at reasonable cost at the time. As I recall, the power was 1-watt or +30 dBm. At 6 GHz, the wavelength is only about 1 inch, so plenty of antenna gain was readily available. 6-ft parabolas were common then and may have been a good cost to benefit trade off. Their gain was near 38 dB at 6 GHz. We tried to limit our path to about 25 miles for reliability and the cost of radio towers. Here is how our path might add up:

Free space loss: -140 dB
Antenna Gain (2ea): + 77 dB
Transmit power: + 30 dBm
Misc. loss (2 ea): - 5 dB

Received carrier pwr: - 38 dBm

A receiver sensitivity
for a multichannel RCVR: -80 dBm
would give us a fade margin of: 42 dB.

How would your system add up?

Best regards, Richard Harrison, KB5WZI

563. Lightning Arrestor Questions

Hello:

The more I read up on this subject, the more confused I get.
Have some pretty basic questions on lightning protectors, if anyone has a spare minute or two.
Would sure apprerciate any clarifications on the following points which I am really confused on.

Will be putting up a simple receive only antenna once it warms up a bit around here; probably a simple Inverted-L type, most likely the PAR EFL-SWL

Have been thinking about incorporating a lightning arrestor into the antenna system Again, this is a receive only application.

The vertical leg of the antenna will terminate in the PAR Balun, which will be pretty close to ground level. I will have a ground bar at that point to which
the Balun ground(s) will be connected.

From the Balun to the radio will be coax.

Looking at the Polyphaser in line coax unit (dc blocked), and also the ICE 300 series units.

Questions:

a. For either unit, is the arrestor placed between the Balun and the antenna, or between the Balun and the radio ? Why ?

b. The Polyphaser unit apparently, when triggered, shunts the charge (only) to the coax shield. The only path to ground would then be up to the radio, thru the
chassis, and then to the AC power ground.

Or, I guess, possibly back the other way via the Balun's ground ? Or both ?
I would also image that the Balun's windings would probably blow too quickly to truly shunt any pulse to its ground ?

There doesn't seem to be any separate ground lug, like the ICE units have from their pictures.

I'm a real novice with this lightning protection stuff, so I am probably missing something, particularly with the Polyphaser shunting-to-the-shield-only approach which
doesn't seem too great regarding how an adequate RF ground is reached for any
diverted strike/pulse.

What am I missing or not considering with the Polyphaser approach ?
Thoughts on ?

c. Any opinions on the Polyphaser vs. the ICE units for a receiving only application ?

Much thanks,
Bob

564. adding some extra wire to existing antenna

Hello Antenna "lovers",
It's been a cold winter so far. I have to plan my
spring/good weather,outside stuff now. I am thinking of adding more
length to my linear-loaded,140ft. dipole. I figured that the antenna
now is 70ft. per side. I been "playing" with the thought of adding
"about,or around",
54ft. to EACH side. These additions to the basic antenna would be
"hooked" about 90deg. to
the plane of the 70ft. side. I've looked at the "double-bazooka"
design,and think that this might get me better results on the lower
bands. I probabally should have just started with a
"full halfwave dipole" for 160m, and then just "hooked" the ends to fit
my yard.
The antenna has a feedpoint up at 55ft. with the ends
at 15ft. It's feed with 450ohm ladderline,to a 4/1 balun,and then good
grade coax. Still working on "that" coax length. I'm needing
50ft.,and I realize that it's length is needing adjustment. I trying a
1/1 balun out tonight. The length of the L.L. is 80ft. Will try 62 to
65ft. when weather changes.
My tuner WILL match the set up now; but it doesn't work as expected.
THE age-old,question; " How can I FIT a BIG,160m antenna INTO a
small yard ? ?

Thanks,

Paladin

Rob, you are unnecesarily complicating matters.

Either you can have lightning strikes in the vicinity of your antenna
or you can have a direct antenna lightning strike.

You can completely separate antenna design from the effects of
lightning. Just erect your antenna according to required radiating and
receiving properties. Inverted-L's and dipoles are simple enough.

If you expect lightning strikes in the vicinity then all you can do is
place a lighning arrestor in the coaxial feedline. Or from each of the
wires of a twin, balanced feedline down to ground. In the case of a
nearby lightning strike, this can do much to protect your radio
equipment but will not guarantee complete protection.

In the case of a direct lightning strike on the antenna there's
nothing you could have done to prevent it. Absolutely anything can
happen to your antenna, equipment, or anything else in your premises.
Including yourseslf. Just assess the extensive damage and inform your
insurance company.

On the other hand, don't completely disregard the hints and tips you
may receive from other conributors to your query on this newsgroup.
But it's all a matter of probability and chance.

Reg.

Hi Bill,

You might actually be right. I think that's what they are trying to do to hams with the possibility of BPL.

I think that AM (as it is) should stay that way FOREVER. I am not opposed to these stations using a parallel form of digital broadcasting (IBOC?) but to turn the AM-DSB transmitters off I think would be a tragedy. It is the only form or radio that can be easily demodulated. A grandfather can sit down with his grandson, a bunch of wire, an oatmeal box, and a few other cheap components and in a few hours have a working (and demonstratable) radio - FREE RADIO - and discounting lightning it is 100% safe too! It's that kind of thing that got me into the hobby - and with the numbers of licensees dwindling and our RF bandwidth at stake it is high time that we get the next generation interested.

First, the comment in another response regarding direct strike is mostly valid. No arrestor will protect from direct strike. [up to 100,000 amperes in less than 1 microsecond, with a 20,000 volt per meter E field.]

Second, for near strike, the arrestor should be installed depending on arrestor design. For coax based designs installation should be between balun and radio. For open wire design it should be installed at the wire to balun interface. Near strike is a non precise technical term. For near strike in the 10,000 E field zone the arrestor probably won't provide the protection you seek. For the 1,000 E field zone you should get some protection.

Why? When the arrestor ignites, fires, actuates there still is a voltage across the arrestor. This is the net voltage from the plasma in the spark gap or in the ionized internal gasses. This net voltage transient has a power density that extends from BC/MF [<160 meters] to the HF/VHF boundary around 30 MHz. It is a broadband pulse. The question is how much voltage can the radio be exposed to without damage?

The best solution is to disconnect the antenna and move it away from the radio when not in use.!!

I'm a retired Aerospace/Electrical engineer who spent years designing for lightning strikes both direct and near strikes. My station is 100% conforming to electrical code and lightning mitigation techniques. Last July, a near strike lightning pulse caused the ground fault interruptors for the pool, the bathroom and the kitchen to function. The circuit breakers in the service panel for the basement power distribution opened, and the power transformer on the utility pole about 1/2 mile away exploded. I lost my ICOM 756 ProII which was disconnected from the power lines, notebook computer, USB damage in a second computer on the in-house LAN, and one telephone. The ICOM 756 Pro II was disconnected from the antennas, and the lightning surge protectors did not actuate. A post fault failure analysis indicated that there was a surge in the utility power neutral to ground. The entire neighborhood of over 50 homes suffered some degree of damage. It is estimated by the power utility that the strike was 1/2 mile away.

My ICOM 746, my Kenwood TM-G707, and the numerous power supplies suffered NO damage. Go Figure :-)

CONCLUSION: Lightning finds way to kill electronics no matter how well the equipment is installed.

THE age-old,question; " How can I FIT a BIG,160m antenna INTO a
small yard ? ? .....

In as most sneaky manner as possible. You could try adding to the
ends. The usual double bazooka is made mostly from coax, and
actually has more loss than using plain wire. The loss gives it the
wider bandwidth. There is no free lunch.. :/ I'm on a regular city
lot, and I've been able to fit in inv L's, and also have a "Z" dipole
that I can use. At the momen, I'm now running a 80 turnstile, and
40 dipole on one coax. On 160, I short the shield to center pin,
and load it as a top loaded vertical. "four 60 ft top loading wires,
and appx 42 ft height of the feedline". For all around use, it's
my best antenna, but sometimes the Z dipole beats it for NVIS
stuff. If you can fit a 80 dipole, you can probably fit a full size
160m Z dipole. Inv L's work pretty well, but I recently took mine
down as it was redundant, and the top loaded worked better most
times. I tried Hi-Q coil loaded dipoles, but the Z dipole was better
here. No inductor loss. No tuner needed either. It's fairly efficient.
But later at night the vertical is generally best for most distances.

I'm trying to squeeze a 75m inverted V into my backyard. My neighborhood is your basic suburban ghetto so there isn't much room between homes (like 10m behind me and less to either side). Anyway, am using EZNEC4 to get an idea of how much power I can run. I am worried about the neighbors exposure level. EZNEC has a serious disclaimer about using the program to determine compliance. I understand the vagaries in accurately modeling the near field and I understand that the author does need law suits. On the other hand, I want an idea of how much trouble I have and if I need to buy an accurate field meter (or if I need to move!). Anyway, the disclaimer makes it sound as if EZNEC4 is worrthless. I assume that it is as accurate as the inputs and assumptions. Right?

On the other hand, if your worried about exposure levels, what do you do to bracket the problem?

Hi. I've heard and read some about ladder line and dipoles.
So what is the basic configuration look like? My impression is
the set-up starts with either a balanced tuner with 400 ohm output
or a 50 ohm tuner with a 4:1 balun to the 440ohm ladder line. The
ladder line then runs to the dipole and that's pretty much about it.

So my EZNEC on my future backyard Vee shows about 60ohm which is about
a 12:1 mismatch at the antenna feedpoint! So do I have something wrong
in the basic config? Or do you all put a balanced impedance
transformer up at the antenna feedpoint?

Just a little confuzed?

Here's what I did and it works very well.

http://www.qsl.net/w5dxp/notuner.htm

An SWR of 12:1 on ladder-line is acceptable but where did that value
come from? 440/60 is 7.3:1. And your 440 ohm ladder-line (Wireman #554)
is probably closer to 360 ohms.

ok, got me. to be accurate, eznec says the feedpoint Z is
32-j68.5...the apex is only 60' in the sky so the feedpoint impedance
is not too high. so that's where the 12:1 roughly came from (i was
playng with the height above ground).

so the question remains, ppl really run a very high swr at the
feedpoint..is there any advantage to matching at both point? i.e.
a fixed balanced impedance transformer up there at the feedpoint, and
then, of course, a tuner down here.

Jim, you can explore the options yourself. My transmission line calculator at http://www.vk1od.net/tl/tllce.php will allow you to specify the load impedance from your NEC model or transformer, and calculate the losses on Wireman 55x ladder line.

For example, if you used 80' of 551 ladder line on 3.6MHz and the feedpoint was 32-j70, the loss would be 0.5dB and the Z at the tx end of the line would be around 380-j1200.

Owen

PS: I am a little surprised how low the R of you modelled feedpoint is... I would have expected round 60 ohms, give or take.

Tuners with baluns in them are inferior to true balanced tuners. Let's
look at your Vee for a minute.
>
> So my EZNEC on my future backyard Vee shows about 60ohm which is about
> a 12:1 mismatch at the antenna feedpoint! So do I have something wrong
> in the basic config? Or do you all put a balanced impedance
> transformer up at the antenna feedpoint?

Assuming 50 feet of feedline a design center of 3800khz, and 31 ohms AT THE
RESONANT FREQUENCY (typical of a 90 degree vee), and a balanced tuner (for
the 450 ohm cases), you can expect feedline losses on the following order:

Belden 8240 (RG58) 0.344db
Belden 9258 (RG8X) 0.276db
450 ohm ladder line 0.102db

The coax losses above are at an SWR of 1.67 to 1, while the 450 ohm ladder
line loss is at 7.5 to 1.

Moral of the story. If you're only gonna use the antenna on 75m, use coax
and be done with it. It's not going to make much difference. BUT...

If you plan on using it on other bands, you might want to consider this:

160m (1.83mhz)

Belden 8240 25.61db (SWR > 13000 at feedpoint)
Belden 9258 24.63db
450 ohm ladder line 6.69db (SWR a bit more than 1700)

40m (7.15mhz)
Belden 8240 8.4db
Belden 9258 7.52db
450 ohm ladder line 0.221db

Note that, even at the resonant frequency and a much higher SWR, the 450
ohm line has fewer losses (but not enough to matter). But where it really
shows up is when you try to use the antenna on bands well away from its
original design frequency.

Of course using an antenna on a frequency well above the design frequency causes the pattern to break up. But that's the price of using a single, untrapped wire on a lot of bands.

The purpose of the EZNEC disclaimer is to prevent people from using EZNEC data as evidence that some level of exposure is or is not safe for personal exposure, for example in a lawsuit. EZNEC results are allowed for use in determining compliance with FCC RF exposure standards.

You're absolutely correct that EZNEC results are only as good as the model and the skills of the person creating it.

I think you'll find that readings you get from an "accurate field meter" can easily be variable and contradictory, and a truly accurate one is likely to be very expensive.

If you're worried about exposure levels, the first step would be to try and determine what level is truly unsafe. To my knowledge, no one has ever established this, but history has shown us time and again that this has nothing to do with what a jury is likely to decide. A good place to start the learning process is http://www.arrl.org/news/rfsafety/exposure_regs.html. Among other information, it reveals the relationship among monkeys, bananas, and the FCC's conclusions about what constitutes a safe exposure level. Good luck!

If you use ladder-line, you generally don't have to worry
about matching at the feedpoint. That's one of the advantages
of ladder-line. Ladder-line handles a 12:1 SWR just fine for
reasonable lengths.

thanks. yes, i agree measuring the field directly is very tricky and
the answer changes daily! Anyway, I've read the ARRL reference before
and my own experience and basic conservativism leads me to be very
careful. Anyway, the law. the OET65 tables, and EZNEC clearly will
allow me to run 500W PEP ssb.
I'll run about 250Wpep. This leaves me below 1/10 the uncontrolled
limit (ignoring duty cycle) except directly underneath and in-line
with the doublet (which by chance is difficult to get near).

Thanks for the time to respond.

12:1 is just about right! What are you worried about? My VSWR on 80 meters is almost 30:1. I get excellent results.

VSWR is NOT bad. I know the Ham Mantra of low VSWR. But, it is a false mantra. Once the antenna SYSTEM [antenna, feedline] is matched you get maximum power transmitted to the load.

584. noise bridge

As I read through the various opinions regarding antenna load,
impedance, etc., most of the arguments seem to be mathematically oriented.

Does anyone use a noise bridge (as mentioned in ARRL pubs) to determine
the feedpoint impedance?

Is there a source for these bridges?

This came up as I am studying for general exam.

Thanks

john

I used to until MFJ came out with their antenna analyizers. I bought
a model 249 which read directly in SWR which is what I was interested
in. The newer ones read impedance also.

> Is there a source for these bridges?

They can be had used, made fairly easily and I've seen kits. I had a Palomar
which I sold when I bought the MFJ unit.

> This came up as I am studying for general exam.

Good luck!

Do not ignore duty cycle. It is one of the most important factors involved. For someone like myself, who listens a lot on CW and does not transmit much, the duty cycle is something like 1% and this makes a huge difference in the exposure results.

250 watts PEP (with reasonable compression) and a talk time of perhaps 25% probably yields a duty cycle less than 10%. (Someone else will probably have a real formula for PEP x compression x average voice.) The averaging time is not always clear in the exposure formulas, and this could make a large difference. What is your duty cycle averaged over 24 hours?

Harry has a small voice/mouse voice. If you're a survivor you may have heard it. It may be technology, projected (from a satellite.) One survivor said she thought she might have an inner alter patterned after Harry. You may have a crown as a receiver (I have a crown of unknown origin, upper left quadrant, near the front.) I heard a Barbra Streisand song in my left ear once. I have a "dimple" behind my ear. Mesh might be part of the conductive system receiving signals from satellites.

Hi Jimg,

Do not bother about the antenna impedance if you want to use it as a multi-band antenna because it will change a lot with the frequency band.

1) First, install a dipole 2 x D, D being the higher length that can afford your backyard. (2 x 20 m is good for 80m band operation)
http://www.barbaxoops.com/modules/xcgal/displayimage.php?album=7&pos=4&pid=4

2) Then you install the ladder (in the middle of the dipole). The ladder should go straight from the center of the dipole to the antenna tuner (in the shack). The ladder can be made of electric wires and PVC pipes as spacers (do not forget to glue them)
http://www.barbaxoops.com/modules/xcgal/displayimage.php?pid=5&album=7&pos=5
http://www.barbaxoops.com/modules/xcgal/displayimage.php?pid=57&album=7&pos=2

3) Finally, you built an balanced antenna tuner. The F3LG type is the easiest to built. The MacCoy (see the following pictures) is the most popular
http://www.barbaxoops.com/modules/xcgal/displayimage.php?pid=46&album=7&pos=0
http://www.barbaxoops.com/modules/xcgal/displayimage.php?album=7&pos=1&pid=47

... as you know, that antenna is called a "Center Feeded Dipole" .... but french people say "Antenne Levy"

Contact me if you want more details about it.

Best regards

I just put up the Buckmaster/Alpha Delta OCF 6 band antenna and so far the SWR is very good on ham bands. I am not yet able to compare it against a regular dipole on those bands, although signals are very good so far. I was a bit leery of these kinds of antennas after learning the B&W put resistors in the center feed to smooth out the swr, for their G5RV version. I do not believe the Buckmaster design does this, it is fed off center at a 300 ohm point with a 6:1 balun, per the advertisment. Anyone else have this antenna? Jim N4BE

Ted,

One way is to place the aerials at a "non 1/4 or 1/8" wavelength apart from each other but VHF is really not that bothered if you are more than a 1/4 away.

If you really want to be sure, just tilt the spare aerial 90 degrees in the horizontal plane. That will limit the interaction even further.

I imagine the spare receiver have a 50 Ohms input impedance but only while powered up! This means that there are no good way to tell whats at the end of the spare aerial...

But, forget about the details and just install the aerials at a more than but at a non-1/4 of a wavelength distance apart and all will be good enough!

Cheers

Dan / M0DFI

593. Larger size HF antenna's

Newsgroup: rec.radio.amateur.antenna

Source record: 65254

Hi,

I seek some help, advise or suggestions on HF antenna's. I've bought a house with a plot of approx 330 x 80 ft / 100 x 23 mtr available for HF antenna's.
But when I research HAM HF antenna's, home build or commercially available, I only find a lot of small, smaller and smallest HF antenna's (eg. wire antenna's, inverted V, T2DF) that don't take full advantage of the size of my land available. On the other end of the spectrum there are plans for very, VERY large antenna's like Rhombic and Beverage. For this size of antenna's my plot is to small.

Do you have suggestions for HF antenna's I should check out? Let me know in this forum or pm me. Thanx in advance. 73

Marteen, the reason for the gap from small to very large antennas is
mainly that the longer ones are developments of long wires and need to
be several wavelengths long at the lowest operating frequency.

However, it sounds like you block is large enough to accomodate a half
wave dipole on 160m... it all depends on the bands that are of
interest to you. Similarly, you migh be able to accomodate an Extended
Double Zepp for 80m, depending on orientation requirements, or an
array of verticals. Don't forget that guyed structures consume space
for the back guys. The space might allow you to erect several towers /
antennas without them all being tightly coupled as is the case with
smaller blocks. Whilst you are working at how to fill the space now, I
am guessing that it won't be too long before the space won't seem
large enough!

What exactly do you mean by an antenna that "takes advantage" of your lot size? The main advantage of a larger antenna over a simple one is higher gain. But you only get gain in one or a few directions, at the expense of gain in other directions. So unless you can rotate the large antenna, you'll have an antenna that works great in a very few directions but typically much worse than a dipole in most others. Is that what you want?

One of the few ways to get both gain and some control over pattern direction is with a phased array of verticals, symmetrically constructed so you can switch directions. Among the sources for information are ON4UN's _Low-Band DXing_ and Chapter 8 of the _ARRL Antenna Book_.

Ok. I am assuming that there is 1 back guy and two front guys (not shown). If you do the structural analysis, you will see why that configuration is not common.

>
>Is there a source for these bridges?

Hi John,

A noise bridge is the same as any bridge used to measure Z. Yes it has a source (if you mean RF source) and it is as the name implies: noise.

The noise represents a wide band spectrum source rather than a fine tuned RF oscillator source. The benefit of this is that you don't have to tune your receiver to the oscillator and be plagued with the frequency drift of either, or both. The noise source guarantees you can tune your receiver anywhere, and there will be a source signal to measure the Z against.

The downside to this is that it takes a lot of Watts into a noise source to equal an adequate mW output from an oscillator. A lot of Watts is not always available, and certainly not any cheaper than an oscillator. Hence, you can suffer from not having enough dynamic source range to find the null balance of the bridge. For some measurements, like tuning an antenna, the noise is sufficient for an average SWR. For other measurements, like measuring Q, there is not enough oomph.

The cheap noise bridges simply use a Zener diode biased near avalanche. (This is why signal clippers, like back-to-back diodes at the antenna terminal, are anathema.) If you think about the bandwidth you want, and the power applied, you will see that you are spreading a few mW across a lot of MHz. Frequently the diode source is amplified through a wideband Amp. Myself, I have a constantly, weakly illuminated Photomultiplier Tube that I use as a very wideband noise source. Very simple concept, but not everyone has access to PMT's.

EZNEC4 computes the antenna currents. Knowing the voltages would be interesting. Unlike the feeder line where the voltage or current are easily determined from the characteristic impedance, the line parameters, and the terminating impedance, how do you determine the antenna voltages? First blush says, uh, 377ohms relates the voltages and current, but that's in free space. The antenna has radiation, inductive, and electric fields (well, the radiation field is actually the transverse electric field component), so how does one go about getting the voltage as a function of antenna position (EZNEC current). I'm sure the answer is obvious but I'd appreciate confirmation (of an answer and my clouded intellect).
Thanks.

You don't. Voltage is a measure of the potential between two points. When those points are separated in space and in the presence of a changing magnetic field, which is the situation near an antenna, the voltage you would measure depends on the path you take between the two points. Crudely and not completely accurately put, it depends on how you orient your meter leads.

First blush says, uh, 377ohms relates
> the voltages and current, but that's in free space.

No. 377 ohms is the ratio of E to H field of a plane wave in free space. It isn't the ratio of any voltage to any current anywhere. There is no current in free space, and voltage depends on the path you take, as I said above.

> The antenna has
> radiation, inductive, and electric fields (well, the radiation field

The current reported by EZNEC is the net standing-wave current
(for standing-wave antennas). That current is associated with
the standing-wave's H-field which can be measured. The standing-
wave also has an E-field. Is there any way to measure the magnitude
and phase of the E-field? I vaguely remember a florescent light
bulb being turned on by the E-field, glowing brightest at the
tip of a mobile antenna.

Hello, and I share your sentiments but technology moves on. You either keep up with it or be left behind. I get nostalgic over old vacuum tube radios like the Collins KWM types or some Drake models but I wouldn't want to be stuck in that period. Lots of wonderful things to discover in the here-and-now, even pour moi (who passed forty about 16 years ago).

There's plenty of electronics out there to interest young minds if you look for it. Ramsey offers some electronic lab kits I wished I'd had as a kid. And speaking of AM-DSB wasn't a spark-gap transmitter using morse code even simpler (well maybe not if you were using a Branly coherer on the receive end and those transmitting antennas sure seemed to require a lot of wire and towers)? I built crystal and one-tube radios as cub/boy scout projects but what I really wanted to construct was a superhet (or maybe a TRF type) since I knew they could pull in lots of stations without requiring an outdoors antenna. For simplicity and ease of construction the majority of those DIY home radio projects excluded the RF and/or IF amplification required to provide a requisite level of receiver sensitivity with an internal antenna. Never built a superhet but I constructed an FM broadcast receiver using a tunnel diode (a componont one of my later Va Tech EE profs would refer to as an "electronic Edsel") as a junior high science fair project. Just a few thoughts. Sincerely, and

Ground Loop. Took time to find it though.

The Astron RS-35 power supply connects utility power neutral to the case. It also connects the 13.8 volt return to the case. [This is commercial common practice but is prohibited in Military Systems design.] Although everything on the operating table was isolated from the utility power and external antennas, everything was connected together by coax braid, connections to the operating position common 'ground', and the 13.8 volt return.

Remember, this strike caused large area damage. Close to 50 homes suffered some damage. Several homes took up to 6 weeks to have their internet functioning again.

The lightning strike tripped all [ALL] ground fault interruptors in the house. The ground loop in my system connected chassis and power returns and coax cable together. The weak link were circuit boards in my 756 Pro II filter and tuner. The boards VAPORIZED. Smoke all over the place. Pungent smell, etc. That failure protected my IC-746, Kenwood TM-G707, etc from damage. [Expensive fuse!!]

I wonder if it also protected my swimming pool pump and heater from damage <grin>?

Hi Dan,

They use ground as a shield, not a current carrier. This is also suppose to be code for commercial and retail electronics devices. Connecting the metal cabinet to neutral was supposed to have slipped into La Brea tarpits with the dinosaurs. Back before polarized plugs, you could electrocute yourself by guessing wrong, touching the metal surface and also being grounded. The bridging between toasters and water taps (or stove tops or fridges) come to mind.

Also common, but nearly as fatal, was the practice of putting two, series capacitors across the AC line into receivers to cut down on noise from the lines. They would also take the tap of the two caps and tie that to the chassis, thus insuring half the line potential was always on its surface, unless you provided a ground connection. This was one of those suicide connections where if you were holding the chassis and pulled the ground lead, you automatically became a fried line fuse. Members of our hobby have preserved this suicide connection by grounding their remote antenna (or equipment) through the coax shield instead of through a separate ground wire (this is why we have codes).

GFI breakers sense the common mode current (that current that has escaped the neutral/hot loop) on the shield path (although it is called a safety ground for 60Hz service).

Maarten wrote:
"Do you have suggestions for antennas I should check out?"

I am listening to Radio Marti and too jammers on the same frequency. Cuba is the target. Who knows where the transmitters are? Marti is said to be in Miami but that is not necessarily its transmitter location. Likewise the jammers may be in Cuba or elsewhere. LocaL Jammers must be much more numerous to cover the same territory for a large area, but they are more effective. The band is 25 meters, about 12 MHz, a year-round performer.

Monitoring Radio Marti in Houston with a small battery portable complete with its telescopic antenna convinces me that a listener is better served using horizonta polarization due to the nulls off the antenna tips which reject interference. The antenna should also be rotatable for maximum signal and, or, minimum interference.

A large antenna is usually impractical to rotate. Curtains and rhombics can have high gain and directionality. You can erect enough of these to cover all azimuths desired, then you don`t need to rotate any antennas. So many antennas are usually not possible for the amateur.

For the radio amateur, an assortment of Yagis mounted on rotators can cover all desired frequency bands and directions effectively and efficiently.

Best regards, Richard Harrison, KB5WZI

These must be very small fishing boats, as ALL vessels over 65 Ft MUST
have two Vhf receivers operational while navigating. Marine ch16, and
marine ch13. this is required by The Bridge to Bridge Radiotelephone
Act.
It really isn't a big deal as long as the two antennas have some
seperation either vertical or horozontal. I have installed multiple
MORAD 156HD antennas on a Masthead Tree, using 24inch Standoffs,
and not had any problems with simulataious operations as long as the
radio's frequencies were seperated by 50Khz or more. Of course I
was working with good commercial type Vhf's like Modar55/75 or
SEA156's, and not the RayJeff consumer crap that one would usually find
on noncommercial vessels.

You'll find information on this kind of antenna in many publications.
It's commonly called a "discone".

Robert 11 wrote:
"For either unit is the arrester placed between the Balun and the antenna, or between the Balun and the radio? Why?

It likely is superflous.

Coax connectors make lightning arrestors of sorts. They clamp voltage to the arc sustaining voltage (less than 100 volts), once they fire. If you are transmitting, r-f may keep the arc alive. Broadcast transmitters sense the arc and shut the transmitter down for an instant to quench the arc. Communications radios usually don`t bother as their transmissions are sporadic and usuallly short.

Remember, coax shield is impenetrable to r-f. D-C conducts right through. R-F does not due to skin effect.

In countless VHF antenna installations atop tall towers around rhe world we never used a Polyphaser or similar arrestor on the coax, yet never had damage to radio antenna circuits, even to transistorized radios.

We always used folded driven antenna elements. We grounded the coax at the top and bottom of the antenna tower. The tower due to its size has lower surge impedance and carries the bulk of the lightning current to ground. The tower is well grounded.

We found it necessary to use brute-force pi-filters on every power wire feeding the radio including the neutral wire. We used tower lighting chokes in the pi-filters to cary the current required to power the radios. We shunted the filter inputs and outputs to ground with MOV`s (across the a-c capacitors).This limited surge voltage on the radio and on the powerline. It eliminated all damage to the power supplies in the radios. These filters were found necessary only when transistor radios were introduced. Before that, the grounded antenna system sufficed for tube-type radios.

Best regards, Richard Harrison, KB5WZI

yoicks!

The latter, I can believe is common practice.

The former - tying the powerline neutral directly to the case -
strikes me as being *extremely* contrary to electrical code and common
sense. It'd turn the supply into a deathtrap-waiting-to-happen if it
were plugged into an outlet having the hot and neutral reversed... and
these are (alas) not at all uncommon.

Now, having the utility power safety ground wired directly to the
case, I can very well believe... this is quite common.

You have enough room for a full dipole at 1.8mhz. That's about 260 feet long and, if you feed it at the center with twinlead or 450 ohm ladder line or 600 ohm open wire line and run a tuner in the shack, it will also function as an extended double zepp on 3.5mhz. Fed this way, these antennas are incredibly frequency tolerant. You will be able to use it right up through 10 meters, but be aware that it will have an increasingly crazy pattern the higher you go. For best low-band performance, you also want it as high as you can get it, depending on whether your interest is DX or NVIS (near-vertical incidence nearby contacts on 160 and 80m). If DX is what you're after, you may want to consider some alternative strategy, depending on how much height you can achieve. But for NVIS, 85 feet is about optimum and the antenna will play well all the way down to around 30 feet. Below that you'll see some ground effects.

If DX is your goal, you may want to consider phasing verticals. On 160m, spacing them about 130 feet apart can make for a fairly steerable array. This would still leave you room for full-size radials on two sides of the antennas. If you use smaller, base-loaded verticals, then you can get away with even shorter radials. On 80m, you actually have a LOT of room.

I once put two Electrospace HF verticals 65 feet apart (E-W) on a lot quite a bit smaller than this. The Electrospace verticals played quite well with just 8 radials each of 32 foot length (about the same as the verticals' height). I brought equal length feedlines into the shack and made a delay box with 65 feet ELECTRICAL length of RG8X in it, cut up into pieces of 1/2, 1/4 and two of 1/8 the total length with dpdt

switches to but them in and out of the loop. Adding one more dpdt switch for reversing the delay to the other side completed the box. This antenna was VERY effective on 80m off its ends. On 40m (they were 80-40-20m verticals), the pattern was more bipolar, but sharper than the more oval pattern on 80m when the zero-delay setting was selected (for N-S) pattern. Similarly, it began to be a bit grassy on 20m. Still, the main lobe of it went the same place on every band for the same settings. And the thing was efficient and had a low radiation angle. It was easily S9+ in New Zealand and Syria from Halifax, NS on 75m. The only drawback was that, with short antennas like that, I had to either tune at the rig and put up with losses on the coax or go out and tune the antennas to cover the whole 80m band. If I had the real estate today, and the gear I have now to tune antennas with, I'd probably try something similar, though maybe in a four-square array for 80. 80 feet is a bit tight for one of those, but you MIGHT just squeeze it in if you're careful.

And render it useless for calling the coast guard, since they are
vertically polarized (unless you hinge it to come up when deployed, but
that's one more thing to break). Basically just make sure they are more
than about 4 feet apart horizontally and that, if really close, the spare
radio is switched off the feeder unless it's needed. If they are mounted
vertically, one over the other, you don't even need to do that. But the
lower one will not be as efficient or effective as the higher one.

>
> You've tweaked my curiosity what does the military do?
>
> 73
> Danny, K6MHE

The general <no pun intended> Military design requirement is the the equipment cases carry no intentional or credible fault currents. [Therefore no inadvertant shocks, in MIL STD terminolgy no personnel RISK, from a hot chassis]. [RISK is assign for personnel, HAZARD for equipment]. Accordingly, the cases and circuit returns are isolated typically by a 500K resistor. There is one system ground point, not a distributed grounding system.

RF circuit design includes isolation between onbly for the output from the low level circuits. Coax shields, shielding on shielded circuits/wires carry no intentional currents and to the maximum extent possible no fault currents.

Example: the output stages of a 5 GHz telemetry transmitter is on a circuit board that is physically isolated from the low level stages and the power source. The isolation may be either capacitive or inductive coupled; in my last design [c.a. 1986] we used 1/4 wave stubs on the same board, top circuit to bottom circuit, woking against two separate returns [top surface base copper versus bottom surface base copper]

In the Nuclear safe environment for example, the primary and secondary of power transformers MUST be 100% isolated and each winding separately shielded with the shields connected independently to the chassis. Therefore a transformer short circuit on the primary cannot propagate through to the secondary. Or, a primary short to chassis cannot propagate to the secondary. And the design MUST include 100% absolute disconnect from primary power in the event of a transformer failure or power out of spec condition. The requirements go on and on and on ...

Bottom line, equipment cases carry no current, share no current carrying path [exception is RF output stages only].

So, the ASTRON RS 35 is not suitable for MIL usage. Now the ASTRON becomes 100% MIL suitable with the removal of just one [1] jumper in the supply [the connection from 13 volt return to chassis. The secondary of the PS is 100% isolated from the primary and the regulator circuits are 100% isolated from chassis]. But, the ICOM radios being powered also violate the MIL requirements and corrupt the system. Remember, HAM equipment is generally operated in COMMERCIAL circuits and must comply with local electrical codes.

From: Robert11 <rgsros@notme.com>
Message-ID: <VJydnS77r6FLTlPeRVn-tA@comcast.com>
Source record: 65186

Hello:

Expect to put up an outside antenna for listening only (30 MHz and below)

Not sure if it will an Inverted-L or just a long horiz length.

Due to the way the property is laid out, and a few other considerations, I will have to bring the
coax from the Balun at the end of the antenna (at, or close to, ground level) back to the house which is about 40 feet away.

The easiest thing for me is to essentially run the coax some distance below at ground level, and directly under the active, higher, horiz length as it goes back towards the house.

How far should/must they be separated such that the coax doesn't influence the active horiz section of the antenna right
above it in any manner ? (listening only antenna).

(my concern I guess is that the coax shield which is grounded will act as another element, or an artificial ground, or... ?)

Thanks,
B.

Hi Bob,

If, as you say, it is already running along at ground level; then this
is not a bad thing. The shield should have no potentials on it -
which means it should act like it is at ground potential.

If it acts like another element, it is merely imitating the earth
already doing that. Upshot of this is that you will notice no
disturbance nor contribution of the shield.

Open line needs spacing from conductive surfaces to be 2ï¿½ to 3 times
the conductors spacing. In other words say the so called 450-ohm
window line whose spacing is 0.8" would need to be kept away from
condutive surface about 5-inches.

It happens at the service panel! White [COMMON] is connected to the non current carrying bare wire at a many input terminal block. The block is then connected to an 8 foot ground rod installed by the utility or your electrician.

It'd turn the supply into a deathtrap-waiting-to-happen if it
> were plugged into an outlet having the hot and neutral reversed... and
> these are (alas) not at all uncommon.

Agree, I found three miswired circuits in this house. I was present at the house inspection and ran the tests myself. The mis-wiring was corrected the day we moved in. [Radio Shack sells a simple tester for this. It is worth checking every circuit in your house or apartment].

>
> Now, having the utility power safety ground wired directly to the
> case, I can very well believe... this is quite common.

Maybe my terms are not up to date.

My electrical service connection is 3 wire 240 volts AC at 60 Hz. Within the distribution panel RED is connected to one feed; BLACK is connected to the other feed and white is connected to the common connection [return]. The common connection is then distributed throughout the house as the bare wire in standard wiring. The common, white and return, connection is connected to an external earth connection [ground] by an 8 foot ground rod.. So, the WHITE wire serves as return for both RED and BLACK circuits and has a single earth connection. So, your 3 prong socket contains connections to power as follows: HOT [either RED or BLACK] circuit, RETURN [WHITE] and GREEN [GROUND] [supposedly zero current carrying. A GFI works on this part of the connection].

In the ASTRON RS 35 the primary wiring has the GREEN connected to the chassis. The BLACK/WHITE go to the transformer primary. This is fine.

The secondary, transformer isolated, has the 13.8 volt return connected to the chassis. It is now possible for the chassis to become part of the current carrying circuit, 13.8 volt return to utility WHITE wire to groud wire. The 13.8 volt return now runs to the ICOM 756 Pro II, ICOM 746 and Kenwood TM-G707. The cases of the three radios and the ASTRON are connected to a common return on the operating table [1/2 inch copper pipe that connects directly to the service panel common return/ground point]. The cases of the three radios are connected together by the braid on the various lengths of coax and the 13.8 volt return. ERGO, a ground loop among the 13.8 volt return, the coax braid, equipment cases and the utility ground.

With a nearby lightning strike that blew the utility 3 phase transformer and affected approximately 50 consumers there are several possible causes of trouble. Among these are imbalance in utility service [i.e. the 240 into the house becomes seriously imbalanced] a lightning induced magnetic transient that couples to all ground loops, or my system was still connected to antennas and power.

I had ALL connections to antennas and power plugs removed except the 1/2 inch copper pipe earth connection at the service panel. My neighbors lost garage door openers, multiple tv sets, numerous telephone circuits, numerous internet circuits, COMCAST had to rewire approximately 1/4 mile of cable tv in front of the house, several homes lost expensive stereo and sound lab setups. In my house all ground fault interuptors activated. And two circuits in my PRO II exploded to charcoal with dust and stench. The LAN blew up, and one computer was lost.

My station was the equivalent of being mounted on a copper sheet, each chassis connected to the copper sheet with bond wires, the 13.8 VDC return connected to the copper sheet [making a loop into the circuits] and the copper sheet was/is directly connected to earth/ground at the power utility panel.

Since I was not connected to POWER or antennas, and the connection to utility common and earth ground are installed to code [circa 1978], I concluded a ground loop that I subsequently found and measured [after the fact of course] was the susceptibility.

Conclusion: Nearby or direct strike lightning causes havoc. Solution: have good insurance. I recovered replacement costs for all except the depreciated computer. I have a specific INSURANCE SCHEDULE on my radio and camera equipment.

There are quite a few programs on the CD that is included with the ARRL Antenna handbook. What exactly are you looking for?? Some of the programs are available from other sources and some like ARRL EZNEC were developed specifically to go with the book.

Nothing in particular, but it seemed as though it might be the best set of
them, so having it would be useful. My questions still remain. What does it
have on it and can it be bought apart from the book?

Yes, that's all fine, and per code.

In US wiring terminology, the green wire is "ground". It's present
entirely for safety purposes - it's not supposed to carry any current
back to the panel during normal operation. It carries current only
in the event of a fault. It's what the external chassis should be
tied to, for metal-chassis equipment with a three-wire cord.

Black is "hot". I'm told that this color was chosen because black is
traditionally the color of death.

White is "neutral". It's the current return for the hot supply. It
should never be tied to the chassis, for two reasons:

[1] The occasional hot/ground reversal thanks to an mistake in the
house wiring. You really don't want your chassis floating at 120 VAC
above local ground.

[2] The neutral pin at the outlet can be pulled several volts above
ground voltage, if some load on that circuit is drawing a healthy
number of amperes, due to I^2*R drop in the house wiring. If the
chassis were tied to neutral, and this occurred, someone might
manage to get a shock if they touched both the chassis and a
truly-grounded pipe or wire.

Ouch! My condolences!

When a strike of that magnitude occurs nearby, I have a feeling that
the Law of Chaos prevails. The current will do whatever it (censored)
well wants to. Even some equipment which is entirely unplugged might
take enough of a pulse via induction to suffer some damage to
sensitive components.

Glad to hear that you managed to recover the cost of replacement!

637. Lightning Arrestor & Protection Of Receiver ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-19 12:52:38 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <CdSdnW2_R4YMFlLenZ2dnUVZ_t-dnZ2d@comcast.com>
Source record: 65198

Hello:

Very interesting comments on my question of a few days ago re lightning arrestors.
Thank you all for trying to educate me on this subject; really find it confusing.
Thread is a bit buried by now, so thought I'd start another one.

I fully understand that the best approach is to (also) just disconnect everything.

But if not around, here's what I don't understand and concerns me.

Assuming a "nearby" strike, and a subsequent emp pulse that's picked up by a receive only antenna
wire strung outside:

No matter how quickly an arrestor's gas tube fires, and diverts the pulse to a good RF ground, the fact that it takes
a few hundred volt threshold to fire makes "any" gas tube type of arrestor almost worthless re the protection of a receiver whose front end certainly won't take a few hundred volts, even for u-seconds, probably.

Do you agree with this statement, or am I missing something ?

Thanks,
Bob

It makes no real noticeable difference in operation, however,
insulated wire will not deteriorate as fast in the ground.

Have you never static shocked a radio antenna? Why was that radio not damaged by up to 18,000 volts? Radios have internal protection which is why those 10,000+ volts did not damage. Parameters are voltage ... and time.

Reason why a well earthed protection 'system' protect electronics even from direct strikes includes internal electronics protection, fast response of all protectors, and how well a protection system is earthed. With properly earthed protection, then protection internal to electronics is not overwhelmed; damage does not occur.

Disconnecting without earthing is not a best protection method. Ham radio operators in the early days would disconnect an antenna lead, put that connector inside a mason jar, and still suffer damage. When that antenna lead was earthed, then damage stopped. Disconnecting - trying to stop a destructive transient - works when the transient has a better path to earth. Most essential is to provide a better path to earth. Disconnecting would only enhance a good protection system. But disconnecting without a non-destructive path to earth has been demonstrated not sufficient. Idea is to keep protection inside that electronics from not being overwhelmed even by a direct lightning strike.

What was more than sufficient to protect telephone switching stations - connected to overhead wires everywhere in town? Gas discharge tubes. We have since obsoleted that technology (depending on other parameters) twice over. But response of a gas discharge tube is not 'too slow'. Too often, people will blame 'slow GDT' for damage when they failed to confirm the most critical component in a protection system - earth ground and connections to that earthing 'system'.

Insulated will reduce corrosion. Don't bury them any deeper than
necessary. Lying on top of the ground is better. Dirt is not a good
antenna element.

I'm looking for a recommendation for an external antenna to use with my

Yaesu VX-7R handheld.

This antenna would spend most of its life on a bicycle (on a rear rack behind the seat), which is how I commute to/from work. However, I'd like to be able to use it occasionally on a car/truck so I'm thinking a

magnetic base would be the most flexible.

Ideally it would cover all of the VX-7R's bands, or at least the 6M/2M/70CM bands and it would have a cable with an SMA connector at the

end.

Ideally it would be something like Diamond's CR627B antenna (http://www.rfparts.com/diamond/cr627b.html) but without needing a triplexor and with a magnet mount.

Now I realize that such a thing might not exist which is why I'm open to suggestions that I drop the 6M band requirement which would lose me the grounding requirement which would lose me the restriction against magnet mount.

Ideas?

greg

I've been experimenting with AM loop antennas, they are directional, and you can "null out" staions by turning the antenna. I have three that are about two feet on each side, and one that is four feet on each side. I use varactors diode to resonate the antenna. I use the antenna to get rid of mid band noise on the AM band. I turn the antenna so it's broad side to east and west.

I've been experimenting with building my own AM receiver, and just found a source for LM3820 chips, which I ordered last night. I need a receiver that is voltage tunable, and covers am, and at least some shortwave. I made one cricuit last weekend using an NE602 as mixer/oscillator, the MC1350 as the IF amp, an FET detector, and an LM386 audio amp. It covered AM, and 49 through 31 meters. That worked on the breadboard, but not when I put it on perf board. Must be my layout technique!

BTW DE KC0FS

To me, it seems like it's the computer dorks that want, and think AM is a dead format. They want nothing but internet crapola. Everything is going digital because it's a cheap, albeit crappy, way to do almost anything.

Wondering what are microwave antennas, what do they do, how do they work, etc?
Are they used in wirless laptops, etc.?
I can use a lot of information on this subject, I have to wirte 3 or 4 pages on this and don't really know much about them need to read as much as possible.

Thanks:)
All information is great!

Fantastic
Thanks for doing that

Now at least I can see what's what in this thing

Cheers

Kev

Bill, I often see the assertion that it is better to not bury radials.

Can you point me to any reputable texts or experimental evidence that shows the difference between shallow buried radials and radials lying "on top of the ground"?

Corrosion is often cited as a reason to use insulated buried radials, but is corrosion a significant risk in most locations. We widely use buried copper water pipes here, and copper clad earthing electrodes for the MEN power supply earthing, yet they don't seem to suffer significant corrosion in most places.

It seems to me that insulated buried radials are likely to be less effective in a lightning protection role.

Owen

Just send me your teacher's email address and I'll submit the report
directly.

Also, send me your English teacher's email address.

You'll find the world's biggest freakin' FAQ site here:

http://www.google.com/search?as_epq=microwave+antenna

Electric fence wire is adequate and cheap. I use it right on the surface,
as you say. It's a bit springy so you may have to work it to straighten
it, though.

Ok, but do you use steel or aluminum fence wire? Galvanized steel fence wire will rust in a few years.

Now this is not a scam, simply send $1.00 from your paypal to
w4jle@w4jle.com. I won't do anything for you, you will get nothing in
return, and if I get enough suckers to bite I will go to OUTBACK Steak House
and enjoy a meal on you.

At least you know this won't cost more than a dollar, you need not worry
about getting screwed, I have already told you up front you are. So get your
guarenteed low cost screw job today!

Sounds like a scam to me! What if I send you a dollar and insist on
medium rare and the next guy who sends a dollar wants well-done? Are
you going to decide? Will you be sending our money back?
Sorry, I see this as only leading to problems. I'm not falling for it.

-Bill

You can use that antenna, and don't need the triplexer. I would suggest looking for an appropriate fixed mount, something which will clamp to the rear rack for the bike, and use the mag base for other vehicles with larger area for a magnet to stick to. The antenna merely unscrews from the mount, so moving (or stealing) it is simple.

We in the business call them "dishes" or parabolic dishes or reflectors.
Shaped like a dish to concentrate the microwaves to an antenna placed
at the dish focal point. Those 8 or 10 foot dish antennas in people's
yards to pick up satellite TV are microwave antennas...

Scott

Owen;

Given the expertise that Bill has accumulated over the years and the
good advise he has given to anyone who asks I think that your attitude
needs modification. When you were in school did you challenge your
teachers this way? I think not. If you diagreed you kept it to your self
or checked it out on your own.

For what it's worth everything that I have read tends towards placing the radials on the open ground, usually staked down so as to prevent tripping or getting caught in a lawn mower.

Dave WD9BDZ

Note to Bill: I know you don't need anyone to defend you but this guy isn't going to take any answer from anyone. I suggest that we drop him as a thread. I just know his response is going to be at me demanding positive confirmation. ;^)..

Dave,

I don't agree, I have never had a teacher worth his salt who responded
to polite questions as Bill did.

No, I don't believe something just because I read it on the 'net, I
would like to know why.

>For what it's worth everything that I have read tends towards placing
>the radials on the open ground, usually staked down so as to prevent
>tripping or getting caught in a lawn mower.

Yes, I see lots of web articles describing that in ham stations, but
it is not the only approach that I see documented and talked about.

In my limited experience, I have not seen commercial HF installations
with radial / ground wires laid above ground in preference to being
buried. The only cases I can recall were because of rock.

Whilst there are articles around about the performance of shallow
buried radials, I have not seen any that deal quantitatively with
radials laid on the ground, or pinned to the ground as you describe,
and the effects of those different installations on antenna
efficiency. That is what I was asking about.

Equally, there a plenty of articles where the author insists that
radials cannot work near the ground and they need to be some distance
above, some stating a quarter wave above.

They can't all have "better" efficiency, the only way to know is to
seek reasons why a configuration is better.

Bill proposed a "better" configuration and declined to explain why /
how it is better.

I used about 1300 ft of insulated copper wire for my 72 radials. I chose to pin mine to the ground witrh fenc e staples. I did this work in the dead of winter. I then also covered them with a thin layer of soil. Come spring the grass grows and the radials are hidden and beneath the applied soil layer so as to not interfere with the lawn mower.

Hi Owen,

These three paragraphs reveal arguments that vary by application,
rather than by degree. It seems to me that most AM stations' ground
fields are shallow buried in gravel simply to permit foot traffic. The
HAARP site uses a grid that is elevated sufficiently to allow
vehicular traffic. Neither really attend lightning as they are more
ground screens and principally constructed for RF.

I found a much more compelling report in:
UNITED STATES DEPARTMENT OF AGRICULTURE
Rural Electrification Administration
REA BULLETIN 1751F-802
SUBJECT: Electrical Protection Grounding Fundamentals
Which is vastly more comprehensive and directly answers these
questions when viewed in the terms of the resistivity of the earth
connection.

Yes, I understand that a ground system may be called upon to perform a
role as the other terminal of a Marconi for instance, and as the drain
for lightning or other EMP. Hence my earlier comment that a rule of
thumb that buried radials should be insulated seems to deny fullest
lightning protection to mitigate a small risk of corrosion.

OK, I found it and it is substantial. It will be an interesting read,
thank you for the pointer. It appears to be focused more on power /
lighting protection that an antenna ground system.

For others, the URL is
http://www.usda.gov/rus/telecom/publications/pdf_files/1751f802.pdf
.

One of the things that intrigues me is the common "expert" advice to
cut radials for 7MHz to 33' long and bury them. It seems to me that
when buried and considering the wire as a transmission line, the
velocity factor will be somewhere between 0.3 and 0.8 depending on the
soil type, so that 33' is likely to be closer to a half wave
electrically, and present a relatively high and reactive impedance at
the antenna base if it were not for the attenuation of the wave on the
radial. It would seem a length more like 17' to 20' would be a better
estimate by the SWAG method (Scientific Wild Arsed Guess), although if
ground attenuation is high enough, it could be cut shorter and the
extra wire used for another radial for a more effective solution.

More when I digest some of the article.

Thanks again... Owen

Hi Owen,

Calling them "tuned" radials is an artifact of their length being described in free space wavelength. The proximity of earth negates such illusions. The association with the necessity of being a quarter wave long comes by the field data obtained by Brown, Lewis, and Epstein. This was simply an arbitrary selection born more of the available wire being portioned out in binary increasing counts (2,4,8,16....) such that 119 radials depleted their stock (short of that magic 128). Their work has been offered on the web through the interests of our discussions here, and by one or several correspondent's scanning and posting their report. Google this newsgroup for that link using the authors as a keyword search. This was offered last summer.

You're asking some good questions.

Many years ago, I was doing some ground system experiments with a vertical antenna. I had strung a bunch of radials, consisting of small insulated hookup wire, on the surface of the ground and I was measuring antenna input impedance. I was surprised to discover distinct resonance effects as the radial lengths were changed, something which I hadn't expected -- they were acting more like elevated than buried radials. It was summertime and the clay ground was pretty dry.

Then I took some pieces of mild steel wire and "stapled" the wires down to conform with the ground and bring the wires into close contact with it. The resonant effects disappeared and the radials acted more like buried ones. I concluded that even a very small air gap between the radials and the ground provided some independence from the ground.

More recently I've done some modeling to try and understand the phenomenon a bit better. I'll give those results in my response to another of your recent postings.

Oh, as for corrosion -- I'm sure it depends on the soil. But there's no harm in using insulated wire, as far as RF ground effectiveness goes. I suppose it would limit the lighning protection voltage to the insulation voltage, however.

Hi Bob,
I'm Ace - WH2T.
Here's my story.
So far I have been very lucky. Neighbors closest on my north and south sides have both been hit, BAD SEVERE strikes. We live on a hill.
I had a strike take out a cheap portable TV that was in the kitchen and it blew a fuse in a VCR. It also came in the telephone line and blew up some FM intercoms that were connected to the telephone line. After that happened I had a commercial lightning arrestor installed by my electric power company at the electric meter.

I use 2 HF antennas, a 272 ft delta loop and a 160 meter band 1/4 wave inverted L antenna, both antennas go thru my MFJ-989C Tuner . When I am not on the air I leave the antenna switch on the tuner in the "Dummy Load"

position. That connects a 300 watt 50 ohm resistor to the radio's antenna jack and grounds both antennas.

The main lightning problems I have had in the 12 years at this QTH are surges coming in the telephone line.
I noticed when I moved here that all the telephone jacks in the house were black. I lost 9 computer modems in short order. I installed the smallest fast blow fuses I could find in both sides of the telephone line (they are under 100 ma) . The next time there was a nearby strike it blew both fuses and still blew my computer modem.
After that I installed three 130 Volt MOVs outside the house in the telephone box , one across the telephone line and one from each side of the telephone line to ground. I also installed a very small pigtail neon lamp between or across the 2 sides of the telephone line. It acts as a gas tube type of arrestor, and lights when the telephone rings, or when lightning strikes nearby; the threshold to fire is under 100 volts. I also installed a DPDT knife switch , to break the telephone line when the computer is not connected to the internet. No further problems. I live out in the country dial up is all that is available here other than expensive satellite access. Anyway , now on to your question.

I got the following Info from another ham.

From my commercial broadcast days the lightning control solution for tall insulated base AM towers (which were always experiencing direct lightning strikes) was to use 2 inch diameter copper balls spaced 1/4 to 1/2 inch from each other (depending on peak RF voltage present) at the base of each tower on heavy arms as a lightning spark gap. Then the 1/4 inch tubing feeding station RF into each tower base would be formed into a 3 turn loop with a 12 inch diameter, with about 2 inch spacing between each turn. I would do the same with the coax feeding repeaters and studio-transmitter links on these towers. I never lost any equipment using these techniques.

I realized I have to mention that I use an inductive RF coupling-impedance transformer in my homemade transmatch in order to eliminate a direct dc path from the ladder line to the transceiver input. I also use high tension teflon coated wire for the primary turns in the transformer. Lightning would be common mode on the transmission line and therefore not inductively coupled through the transmatch. The issue then becomes voltage breakdown between transformer primary and secondary windings (along with minor capacitive coupling), hence the teflon coated wire.

Concerning possible lightning on the ladder line, I use adjustable spark gaps from each conductor to ground outside of my building.

I hope this is of some help.

Modeling clearly shows that using elevated radials which are too long degrades the efficiency. A quarter wavelength can be determined by constructing a dipole at the height of the proposed radial system and adjusting it to resonance. The maximum length of the radials is half the length of that dipole. If you make them longer, efficiency drops. Very close to the ground, the length of a quarter wavelength decreases substantially, so a free-space quarter wavelength can easily be too long.

Modeling presents a very idealized situation, overly so when dealing with ground. But I believe the general trends and conclusions are instructive. I modeled a 40 meter vertical over average ground. It had four 34 foot radials, which were quarter wave resonant when elevated very high. As I lowered the radials from one foot high to 0.1 inch high, the gain dropped 4 dB. The main cause of the drop was that the radials were becoming too long at the low height above ground. Shortening them to 19.6 feet, the resonant length at that height, increased the field strength by 2.45 dB. Burying them lowered the field strength to 1.7 dB below the field strength when 0.1 inch above the ground and of proper length. There wasn't any substantial change in field strength as the length was increased beyond about 30 feet, or when the depth was varied from 0.1 to 6 inches. These changes in field strength are solely due to changes in efficiency; the pattern shape stays the same.

When modeled at 0.1 inch above the ground, the radial current distribution is approximately sinusoidal, as in elevated radials. When buried, even an inch, the current decays in an approximately exponential fashion away from the center. In the case of the modeled antenna system, the current was substantially zero beyond about 40 feet.

Conclusions are:

1. A small number of radials just above the ground are theoretically a bit more efficient than the same number of buried radials, providing that they're not longer than a resonant quarter wavelength at that height. I say theoretically, though, because I believe it would be impossible to maintain current balance in the radials at a low height. So one or two radials would likely hog all the current, resulting in a less efficient system.

2. Making elevated radials too long, even if the elevation consists of being just above the ground, can seriously reduce the antenna efficiency. Buried radials, on the other hand, are insensitive to length provided they're sufficiently long. This latter fact is well known. I've found in other modeling I've done that making elevated radials shorter than a resonant quarter wavelength doesn't negatively impact the efficiency. So if you have to guess, guess on the short side.

The amount of differences you'll see in real antenna systems will vary quite a bit depending on ground characteristics, frequency, and number of radials. And it would be impossible to suspend radials precisely over a perfectly flat and homogeneous ground as I've done with the models. But I believe the conclusions are valid.

You seem to be referring to the feedpoint impedance of a
single radial the virtual impedance of which would depend
upon the magnitude and phase of the forward and reflected
wave on the radial wire. The single-wire transmission line
formula gives a Z0 for each radial as less than 100 ohms.
Given the probability of a high degree of attenuation and
the number of radials in parallel, the impedance presented
at the base is likely to be relatively low no matter what
the length of the radials assuming an electrical length
of longer than 1/4WL.

NEC studies of a 1/4-wave vertical radiator working against three 1/4-wave horizontal radials at 120 degrees, when all elements are elevated 12 feet above a perfect ground plane show virtually identical peak gain as when the same radiator minus the radials is mounted with its base at the perfect ground plane, and connects to it though two ohms (about the same ground loss as produced by 120 buried radials, each 1/4-wave long).

As few as four elevated radials have been used at AM broadcast sites where a typical system of 120 buried radials was impossible due to rocky terrain. The FCC "efficiency" of these radiator systems meets/exceed FCC requirements for radiation at 1 km.

Conclusion: a few elevated radials can be the electrical equivalent of a classic "Brown, Lewis & Epstein" system of 113 (or 120)buried radials.

=======================================

Owen, you may be interested in Program RADIALS3.

Once radials are buried in the ground, just below soil surface, I don't think depth of burial matters very much. But things happen very fast when resting on the soil surface and conductor height is raised only slightly.

Consider a single counterpoise wire. When resting on the soil surface propagation velocity along the wire is about half of the free space velocity. Propagation velocity increases fast as height increases. When height is greater than length the VF is very nearly 1.

When resting on the ground there is an equivalent loss resistance distributed along the wire due to the mutual impedance with the ground. The input resistance at resonance is high. Q is very small. But a lot depends on soil resistivity.

With increasing height the coupling with ground decreases and so does the input resistance. When height is greater than length the input resistance is due only to conductor loss resistance and resonant Q is high.

Resonant frequency increases with height due to the increase in VF. The increase in VF is due to decrease in capacitance to ground when considered as a transmission line.

Changes in capacitance, VF, resonant frequency, and induced loss in the ground, mostly occur in first few inches of height above ground but cannot be neglected until height is roughly greater than length.

Source record: 65147

I have had a 75 meter loop up and down for several years. I guess I try a different antenna every once and a while and always end up putting my loop back up since reports are always the best. I feed it with 450 ohm line and use it on all bands. I even had good results shorting the ends together and using it on 160 meters.

Now my question, I would like to get up a loop on 160 meters. But my measurements I am only going to be around 450 and maybe can get it to near 500 feet which is probably 50 to 100 feet or so short. I will be using 450 ohm line. Does anyone know of what kind of results I might see with this length of loop? Should I just stick with my 75 meter or will I see any gains going bigger?

From: Bob Bob <bob3bob3@cox.net>
Message-ID: <vvd7a3-30d.ln1@p400bob.personal.cox.net>
Source record: 65151

Hmmm

Well I can see that the term doesnt have a rigid definition as such. The antenna part is obvious and I hope doesnt need me to elaborate. The word microwave generally means a "small wavelength", probably anything higher than the frequency of 1Ghz but it may be defined more accurately elsewehere. The wavelength is inversely proportional to the frequency and at 1GHz is about 300mm.

Microwave communciation is generally characterised by short distances and line of sight or visible paths between one end and the other. Examples might be mobile phones (900MHz, 1.8GHz, 2.4GHz), WiFi computer links (2.4GHz, 5.6GHz), high capacity data links (2-25GHz) and so on. (1000MHz=1GHz) Once the path becomes obstructed or goes over the horizon the signal gets severely attenuated.

Antennas are designed and manufactured for the service and range required.

- Something to control a toy truck with you'll want to radiate in as wide as a coverage angle as possible. When you tilt the controller back and forth you still want it to work. Keep in mind that microwave radiation also reflects of objects pretty well, so for short range this is often the mode of operation.
- A WiFi antenna on a laptop and a users mobile phone generally needs to radiate in a roughly horizontal direction but at every azimath. By concentrating the radiation in a desired direction you get better range or can get away with using less power. The WiFI and mobile phone base station on tbe other hand may have more stringent radiation and directionality requirements. The service area may be deliberately restricted by the choice of antennas
- A high capacity microwave data link will pretty well always use high gain high directive antennas at each end. This is so you can make the signal work (say) upto 50km with low power. It is also very important for these links to only have a direct (non reflective) path between each other. The extra time delay introduced by a reflection can foul up the link operation. (You may have heard the term "multipathing")

Generally speaking an antenna is made up of half wavelength elements at the desired frequency, arranged to concentrate the radiation in the desired direction. (look up the antenna terms 'colinear' and 'yagi') More in common use are antennas that use large reflectors behind the element connected to the cable. (look up 'parabolic dish', 'gridpack' & 'patch antennas'. What you see on a comms tower is the same theory of operation as a deep space tracking dish.

The theory of operation of a microwave antenna is pretty much the same
as an antenna made for a lower frequency, just everything is much smaller!

From here on in you'll have to do some research on what antenna gain is
and how to build it into the structure.

Cheers Bob VK2YQA

I use one rather often as a means of tuning my antenna for best reception on HF (not transmit). I have had a general or 2 test my assumption and they seem to hold up (with some minor tweaking to clean up stray impedances).

>
> Is there a source for these bridges?

mfj makes a nice antenna noise bridge. its simple to use too (only 1 knob - power).This device is used concurrently with a tuner for best results.

Note the voltage on that fuse. No matter how fast it is, if a transient exceeds that voltage, then the fuse remains a conductor. Furthermore, destructive transients occur in microseconds. That fuse takes tens of milliseconds to open. Two reasons - both numbers - that demonstrate why one cannot stop or block destructive transients.

Meanwhile, the phone line should already have a protector installed for free that looks something like boxes at:
http://www.alarmsuperstore.com/bw/bw%20connectors.htm
But again, the protector is not protection. A protector is simply a connection to earth. If that box is not properly earthed, then a transient will seek earth ground, destructively, via household appliances.

Most destructive transients enter on AC main seeking earth ground. Incoming on AC electric, into telephone appliances such as portable phone base station, fax machine, computer modem - or that intercom. Then outgoing to earth ground via telephone line. To have damage, first, a path to earth ground must be both incoming and outgoing through damaged electronics. Incoming on that intercom AC electric; outgoing via phone line. It also explains why some appliances are damaged while others are not.

But again, what is the protection? Earth ground. Fuses, power strip protectors, and anything else that will 'stop or absorb' a surge is myth. Ben Franklin demonstrated the solution in 1752. Give a transient a better (shorter, low impedance, etc) path to earth so that it need not find a path, destructively, via electronics.

Those fuses only might blow. And if they did, maybe 300 consecutive and separate transients could have already damaged the electronics. More often, fuses trip due to and after damage created by a destructive transient. If one suffers damage, one discovers why the dwelling was not properly earthed. Why was lightning seeking earth ground inside a building? The answer is often directly traceable to human failure. Protection is about earthing before a transient enters the building.

Ace, WH2T wrote:
"I realized I have to mention that I use an inductive RF coupling - impedance transformer in my homemade transmatch in order to eliminate a direct d-c path from the ladder line to the transceiver input."

Lightning is a threat to antennas and to items connected with them. Static charges may build in a time of clear skies, especially ahead of a thunderstorm. Guy-wire insulators often flashover to announce a storm is approaching.

Radio towers in broadcast stations get lightning strikes over and over again, but loss of equipment or even air time is minimal.

The beacon atop a tower is most exposed, but it is protected by a vertical metal rod attached to the tower near the beacon and extending well above it. Often this rod is an 8-ft Copperweld groundrod bolted to the tower with its tip point skyward. Pits on the rod show it takes hits. Beacon survival shows it does not take hits. The protection works.

Guy-wire insulators are often doubled or tripled at the tower attachment points to discourage flashovers here.

An air gap is provided across the tower base insulator. In theory, lightning ionizes rhe air in the gap and shunts the charge to ground before it gets into the feeder system. Spacing is usually adjusted to only slightly wider than the gap will breakdown on the transmitted signal. I`ve examined many of these ball gaps and horn gaps and seen no evidence of flashover.

To discourage lightning, a turn or two is often made in the conductor feeding the tower. I haven`t seen pts on the balls or horn gaps indicating that the tiny inductance added by a turn or two in the feedwire does any good.

A static-drain choke which has a very high impedance at the operating frequency, but has a low d-c resistance, is often connected across the tower`s base insulator on the line side of the base impedance matching unit. It may be placed on the tower side of the matching unit if there is no d-c continuity through the matching unit.

All the stations I`ve worked in had an air-core 1:1 coupling transformer in the tower matching unit. Primary and secondary share the same axis but are seoarated by a metal rake which serves as a Faraday screen. It is a picket fence between the coils. The tines of the rake have no electrical connection at one end, but the backside of the rake connects all the tines together and firmly grounds them.

The rake allows magnetic coupling between the coils but prohibits electric field coupling between the coils. The rake is a very effective lightning stopper. It is full of pits where lightning has struck.

Best regards, Richard Harrison, KB5WZI

When lightning directly strikes either the antenna or the dwelling,
despite all the precautions, ANYTHING can happen.

The direct strike is just as likely to be on the dwelling and its
occupants as the ordinary radio antenna.

So concentrate precautions on your house, the more valuable of your
possessions. Only then think about your inverted-L and your radio
equipment.

Just a logical way of thinking about things.

A direct strike will probably never happen anyway.

Same here Cecil.

The young kids don't have a clue about Social Security, because it isn't important to them at their time in life, nor was it for me when I was 25. None of us ever thought that we would live to see 65, hence it was just like income tax, something that you simply had to pay.

The problem is not for us elders, but for the younger people who will hopefully someday reach 65. Today, most of these kids don't realize is that the fault with the Social Security system is not in its basic design, but what I beleve is called SSI that allows anyone regardless of age to claim benefits unser Social Security by claiming some form of disability, even if they have never contributed to the system.

Just as an example, when I went to the Social Security office to claim my earned beneits, I was the only American present in the waiting area containing roughly 30 applicants. Most of these individuals were there seeking SSI benefits, few were American citizens, and most had never paid a dime into the system. This is precisely the problem that Social Security faces.

No wonder Social Security is in trouble. It is comparable to a corporation that pays dividends to people that don't even own stock in the company!

'Nuff said on that subject.

Curmudgeonly yours, Harry C.

Reg, G4FGQ wrote:
"The direct strike is just as likely to be on the dwelling and its occcupants as the ordinary radio antennas."

True, unless the antennas are much taller than the dwelling. That was the case of the radio stations. Occupants were safe, protected by the tall radio towers. Just as the towertop rod protects the beacon. the tower protects the nearby structures under it (within its "cone of protection"). Agreed that people are more important than radios. I don`t want to cede people or radios.

Here on the Gulfcoast of the U.S.A., the climate is semitropical and thunderstorms are abundant. Radio towers are struck by lightning repeatedly by nearly every passing thunderstorm and these are frequent.

Where I`ve worked, buildings on the station`s property were never struck, nor was a serious electric surge ever transmitted into any building other than one of the "dog houses" at the towers where it is expected.and prepared for the stroke.

The buildings on radio station properties are protected by big lightning rods, the towers, just as Benjamin Franklin predicted in 1735.

Here's a data point for all. I'm taking down my 102 ft dipole
and putting back up my 130 ft dipole. I measured the resonant
frequency and feedpoint impedance of the 102 ft dipole both
while hanging in the air as a V and laying on the ground.

Hanging in the air: Resonant at 4.52 MHz with a feedpoint
impedance of 22 ohms.

Laying on the ground: Resonant at 2.17 MHz with a feedpoint
impedance of 108 ohms.

Laying the insulated wires on the ground resulted in a
reduction of VF of about 50%. The marked increase in
feedpoint impedance was due to the attenuation of the
reflected waves arriving back at the feedpoint and
agrees closely with my calculations of such.

I forgot to say: Note that the dipole laying on the ground
was close to one wavelength, yet the feedpoint impedance
is not all that high. It would appear that 1/2 wavelength
buried radials do NOT present a high impedance.

Hi Scott, on the low bands you are not going to see much gain. What
you should shoot for is efficiency. On the low bands, the longer the
better. Feed it with 450 ohm line and an efficient antenna tuner and
you should be OK with the dimensions you have available.

Very sorry Owen. My mistake.

The name of the program is RADIALS2.

It deals only with buried radials.

I am at present trying to write a program about coil-loaded
counterpoises and artificial grounds at low heights. But it's a beast
to model mathematically.

Reg.

"Cecil Moore" wrote
It would appear that 1/2 wavelength
> buried radials do NOT present a high impedance.
>
==========
Cec,

. . . . as demonstrated by program RADIALS2

which treats radials as transmission lines. As they truly are.

The permittivity of soil surrounding buried radials is high. It is due to the moisture content of the soil. Water has a high permittivity K = about 80. If the moisture content is 20 percent then the permittivity is roughly K = 16 plus a little bit for the dry content.

The poor, low conductance of the dielectric material, in conjunction with wire inductance, also has an effect.

The soil is mainly, minute rock particles and a little air. Rock has K = 4 or 5. Air = 1.

Velocity factor of any transmission line = 1 / Sqrt(Permittivity).

In some circumstances, there may be no point in having radial lengths longer than 1/10th or 1/12th of the free-space wavelength.

If the soil has any magnetic material in it then the velocity is even lower. But it's a waste of time trying to tune buried radials by sprinkling iron filings around your garden.

The attenuation along buried radials is usually so high that even 1/4-wave resonance doesn't show up. Impedance versus length at low HF is a smooth curve approximately equal to Zo. But input impedance of a set of radials is NOT equal to the impedance of the individual wires all in parallel. They interact with each other. The Law of Diminishing Returns applies.

In perfectly dry desert sand with a resistivity of 5,000 or 10,000 ohm-metres and K = 3, the 1/2-wave resonance may appear on an impedance vs frequency curve. Program RADIALS2 shows this effect as evidence of reasonable modelling accuracy.

This is a case of ground loss decreasing as soil resistivity increases further. It appears attenuation is a maximum when soil resistivity is around several hundred ohm-metres (377?). Which is quite a poor soil.

(I once had a garden of sandy soil. Resistivity was 400 ohm-metres
even in wet weather. Eventually I moved house. SR fell to 70. On the
160m band 7 radials, each about 10 feet long, plus the cold water
pipe, were good enough with a 3/8 wave inverted -L. I never tried
B,L,E's 118 radials, 1 wavelength long.)

But in bone dry sand-desert soil, just rock mixed with air, at low HF
one would not use a system of radials under a 1/4-wave vertical. The
antenna could be a horizontal dipole lying on the ground. ;o)

>
> Thanks,
> B.

Yes it is frequency, time and location dependent. If you haven't already, look up a LUF/MUF calculator and try it out. Inputting the solar flux data, your location and the location of the broadcast transmitter gives you a time graph showing the LUF (least useable frequency) and the the MUF (maximum useable frequency). Simply put, the MUF shows the highest usefull frequency for tranmissions from that location at any particular time. If your desired station frequency is higher than that, forget it. Also, if the LUF is higher than the MUF, you wont be hearing anything from that location until solar conditions (or the time of day) changes. It's an informative way to see how the solar conditions, time of day and propagation path affect what you can hear.

Wow there GBrown,
Don't blast Harry C. He has a point. Up here in the great white north
known as Canada, I have seen deadbeats claim Social Insurance.
They do nothing to contribte to society, they just wait for 'check day'
to pay the rent, and blow the rest on beer and drugs only to be broke
in a day or two until the next month*. My taxes go towards paying them.
Is that right? I think not. Is it the same in the states? If one day I
need to
do the same, rest assured it will NOT be wasted on beer and drugs. I
have paid into this for many years. I would just want something back
from
all the $$$ I had deducted from my pay should I ever need it.
Tom the Canuck.

* Do they eat food? Utilities? I do not know and do not want to..
What they do for the rest of the month is beyond me.

GBrown, the fact that they couldn't speak fluent English may have prejudiced my conclusion. It isn't very clear to me why the Social Security offices need interpreters. After all, anyone who has been in this country sufficiently long to seek Social Security benefits should at least be conversant in English, since that is the language that is spoken here.

When you see many people who appear to be under the age of 30 and cannot speak fluent English seeking SSI benefits, the red flag should go up for everyone. Where is the Green Card? Damn, what was wrong with the Ellis Island immigration procedure, and why did the US eliminate it? At that time your entry into the US was judged on your health, skills, and ability to provide for yourself and your family in the United States. During that era, no one came to the US for a free lunch, unlike today.

Realize that unless we secure our borders and return to the strict immigation policies of circa 1910, the US will become a human dumping ground for misfits from the balance of the world, and constructive citizens will no longer be able to support it and flee to other nations who, for the above reasons, close there borders to other than those that can contribute significantly to their country -- and for good reason.

I am pissed off because some of those "new arrivals" are immediately able to collect larger benefits from Social Security than I who have been paying into the system for more than 50 years! Yet, we wonder why Social Security is about to go bankrup! Dhuh!!!!

Sorry for the curmugenous attitude, but the pot of US money has limitations, and I believe that it should first be utilized for the benefit of US Citizens who have contiributed to the system for many decades, and not be wasted on on freeloaders who have obviously never made any contribution to the system.

Curmudgeonly yours, Harry C.

Hey John,
I like your post. Good idea.
What about those telemarketing companies that sell
worthless products from Canada to the US?
There is a telemarketing company in the building where
I worked. Being a smoker, I got to know a few of the
frequently replaced telemarketing sales staff.
The company in question sells a 'directory' of businesses
in the states. While smoking, I asked one of the sales people
what the product they were selling was good for. The reply
was toilet paper. I would tend to agree. I believe there were
several complaints to the attorney general of a particular state(s)
and I had a smile on my face when the local police raided their
place of business. Too bad they were back up and running the
very next week. How can we stop these assholes? It puts a bad
name on Canada. I feel ashamed that they can operate freely here.
Tom the Canuck.

Harry, I understand your point, completely. I was getting at the fact that how are we to judge who or who isn't eligible for SSI. I worked all my life and it wont be long before I can step up to the SSI office and sign my forms. I wish there were a way to weed out the imposters but you have to start home. There are people in this country, citizens, that take full advantage of the soft hearted liberals and reap the rewards. I really don't know if there is a good fix to and old problem.

amdx, you posted:

"And speaking of curmudgeons, Andy Rooney said
" Happy birthday?--I DON'T THINK SO."

I must have missed seeing Andy say that, but it's so true that it made my day! Thank You!

I believe that it's somewhere after the age of 60 that the "Golden Years" are said to begin. In reality, the "Golden Years" consist of stays in the hopital where various parts of you are being removed. For recreation you begin to give things that were once precious to you to good friends. You worry about gas and electric bills, and tax bills, that essentially double yearly, and you're on a fixed income consisting of Social Security and a pension fund (if you have one). One day you realize that you're nearly 70 and no male member of your family has lived for more than 72 years. You still have a sex drive, but your wife hasn't since menopause. Then you realize your mortality and begin to complentate methods of disposing of your remains that don't present a burden on your family, like donating your body to science. When you go asleep at night, you wonder if you will wake up in the morning, since you hope that when you die it will be painless and in your sleep.

On the positive side, what helps to keep my spirit alive are both my Masonic and fireworks friends who both inspire me to accomplishments and dreams, as minimal as they may be. The computer helps a great deal, because the Internet has become what I had imagined 40 years ago -- a vast source of information.

Then too, I have again pontificated far too much, and if you are approaching the, welcome to the Golden Years! :-)

Harry C.

Why kill yourself when you can stay alive and fight this crap.
No need to resort to physical violence (I don't like the idea)
but instead use our intelligence to fight back.

Why not swamp the offender's inbox with e-mails.

SUBJECT: "How to make a million dollars easily from your home"

INSTRUCTIONS (body text):
Send me $2.00 by mail and I will send you complete instructions to be rich
quickly.
Please include a stamped self-addressed envelope.

(IMPORTANT: Get a PO Box for the address)

Your snail mail reply:
"WHAT TO SEND TO SUBJECT ON PAPER (they paid for it):"

SNAIL-MAIL SUBJECT:
(use this for your e-mail)
How to make a million dollars easily from your home

What to do to start::
SEND THIS E-MAIL:
Send me $2.00 and I will send you complete instructions to be rich quickly.
Please include a stamped self-addressed envelope.

{Insert your address here}

WHAT TO DO:
Mail the above paper message when you have $2 and envelope.

-

This can also work if you take out a classified ad in a local news paper.
There should be at least 1,000,000 morons in a large metropolis. Just send
the

same info but change it to say 'take out a classified ad'.

-

Why not sell 'solar powered cloths dryers' for $50.
Ship the sucker a cloths line. Technically you are not
in the wrong. It is 'solar powered' after all, unless it is
a cloudy day.

-

Give back some crap to the target who has been cross posting to various NG.
I was amazed to learn I posted to rec.radio.amateur.* groups. Your replies
were
there as well. I may check them out, it has been a long time since I made an
FM
transmitter.

==========
{back to pyro for a moment}

Just a thought, I know about the electric firing panel for pyro displays.
Lots of wires and switches. Is there any need for an RF ignition system?
It could cost a few more $$$ but you eliminate the long run of wires from
the
panel to the pyro items you want to ignite. A secure comm protocol would
prevent ignition by 'outside' sources. A laptop could be added to control
the
timing of events.to be fired. A simple User Interface to make it moron
proof.
What do you guys think? Just looking for ideas. Start another thread if you
like the idea. We can discuss details. I have made embedded systems for
about
the last 20 years. This idea is possible.
==========

Sorry, feeling a bit malicious tonight, (===pyro thought not included===)
Tom the Canuck.

P.S. $2 will NOT work in Canada.
We have those $1 and $2 coins to deal with.
(Maybe up the cost to $5 CDN)
$50 should work out just fine.

Mr. GBrown,
In a sense I do not care what creed, colour, or nationality a person
comes from.
We are all human and live on this tiny blue marble called Earth.
{yes there are assholes in every group, even yours, ignore them, I do}
Let us judge by what a person does, not where they come from. Does it
matter?
If you contribute to our "society" (needs improvement) they are fine, if
they live off
the labours of others I object. Perhaps we should adopt the thinking
that we are all
one people on this planet. Are you going to blast me because my parents
came from
Estonia? (If you don't know where it is, look it up)
Ignorance and prejudice are rampant on our planet. Can we not do better?
What about your "equality and liberty for all" in your constitution? Did
that include
owning slaves from Africa? Open your eyes, see the world for what it is,
embrace
other ideas from other cultures and learn from them. Tunnel vision is a
downfall for
the existence of mankind.
This is what I think, you may thing otherwise. I can not stop you from
thinking the
way that you do, you can not stop me from thinking my way.
Tom the Canuck.

719. About Benjamin Franklin and Lightning

The USA Mint is releasing two silver dollar collectables on Franklin;
one, as scientist, the other as statesman. The coins are available in
either Silver Proof or uncirculated condition.

Quoting from the article: "If Comet had claimed that the CHA-250B
was a world-beating miracle antenna, we would have blasted it with
both barrels. Comet doesn't make such claims, however. Comet's
literature merely states that the antenna will radiate a signal
and provide a low SWR on all bands without the use of radials.
In this respect, the CHA-250B performs as advertised. It is neither
a miracle nor a fraud." (The article says it's about equal to a
mobile whip antenna.)

Just a guess, but I'll bet that thingey down at the bottom of the
antenna is a resistor. Although it says it doesn't need radials, they
would help, although they might mess up the broadbanded appeal of the
antenna.
Gary N4AST

729. 8405a working and measuring resonance?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-21 21:53:57 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <BbWdnVM-DdbIME_enZ2dnUVZ_sidnZ2d@comcast.com>
Source record: 65090

Well, After many trials and much learning I believe the 8405a is currently working and actually making measurements. The breakthrough was a web article showing Tau ranging from -1 to +1. This finally made sense of the comments posted here.

Now to the setup and the measurements. I have built a loaded vertical for 2 meters and placed it over a 3 foot by 5 foot ground screen. The exact frequency of the antenna is unknown. This is assembly moved into another room and connected via an unknown length of 50 Ohm cable. The technique is labor intensive, but in the end produces consistent results.

The 8405a is connected to a dual directional coupler. The connector lengths are tuned to produce zero phase. The coupler is driven by a signal generator and connected to the antenna assembly.

Now the tuning process: It involves tuning the antenna for a zero phase return and then temporally replacing the antenna with a 25 Ohm terminator. The 8405a is set to zero phase adjusted to he terminator. The antenna is then re-substituted for the terminator and the frequency is adjusted to produce the next zero phase. The cycle is the frequency is adjusted to the antenna and the meter zeroed phase adjusted to the terminator. This is repeated.

The first attempt did not resolve. That is it the values did not trend toward a common frequency and phase. However the second attempt, which was just a few MHz away did. The result was a measurement that was consistent and repeatable. The meter was set to the 6 degree scale and the measurements were sensitive to 5 kc differences in frequency. The results were consistent to 1/5 a degree.

The Smith Chart shows for a purely resistive load that the return phase from a fixed cable and frequency is independent of R. That is the return phase is constant for a frequency, fixed cable, and pure resistive load. That would imply that when the phase return is the same for a resistive load and an unknown then the unknown is a pure resistive load. This is a way to normalize the effects of an unknown cable to determine resonance.

I think this actually works. Is there a better way to do this?

Thanks - Dan

There is a sizable market for such an antenna.

Those living in dwellings with no possibility of running a dipole or a ground plane antenna with radials would be glad to get on the air with this antenna. Naturally, the higher the frequency, the better it will work.

As most of us know, when the higher frequencies are "open", it doesn't take much antenna or power to work the world.

There probably is a resistor shunted across the feedline. I would imagine
that it is emulating a half wave end fed antenna. That should not be too
difficult to manage.

For someone in an impossible situation for a real antenna, it would work
quite satisfactorily. After all, it is either this antenna, or one like it,
or no operation at all.

736. Vertical on a tower

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-21 22:17:12 UTC
From: Cecil Moore <mycall@arrl.net>
Message-ID: <HpyAf.13426$H71.9215@newssvr13.news.prodigy.com>
Source record: 65097

I'm putting a vertical back up for transmitting and will
probably receive on my horizontal dipole. The vertical
will be mounted on the top of a 30 foot Rohn 25G tower
with the base grounded in cement. The question arose in
my mind whether to connet the drooping elevated radials
to the tower or not. To my surprise, EZNEC says that RF
current flows in the tower whether the radials are
connected to the tower or not. I'm using mininec ground
for the simulation. The radial fields are obviously
inductively coupling to the tower. Does anyone else
worry about such things?

I always answer them really loud, then I tell them to hold on while I get my hearing aid. Wait about 5 minutes and say hello again really loud. If they are still there tell them the batteries are dead and to hold while you get new batteries. Wait 5 more minutes and once again loud hello, if they are still there cuss and say you got the wrong batteries and their not working...

You get the idea, totally frustrate them. I have never had one wait beyond the initial getting the hearing aid.

There's no reason for the tower to be part of the antenna, so I would suggest not connecting them. Some current will flow in the tower due to close proximity induction, but don't make it worse than necessary. Hopefully the tower is not resonant on any band to avoid additional losses.

I have never been a fan of store bought antennas. Never owned one
except a 2m mag mount. I don't know how much this one costs, but I
think there are numerous ways for city dwellers to get more bang for
the buck.
Things I have done: Use a 8-10 foot vertical piece of wire fed with
an "L" network at the base. Work this with your car or pickup as a
ground on 20m-6m. Should work every bit as well as a Comet on these
bands.
On 80m and 40m I have used a 33' vertical in the bed of my truck fed
with an "L" network and had good results. Leads me to believe that the
33' would work well with a modest ground system. The Comet is 22' feet
tall, and I would think a real dog on 80m and 40m.
The only advantage on these bands for the Comet is a broad bandwidth.
I think a 33' vertical with a minimal ground system would beat this
antenna especially on the low bands. Lot cheaper.

Unfortunately, the tower is close to resonance on 40m, my favorite
band. Even with elevated radials at 30 feet, it is 0.8 dB down
from a ground mounted vertical, according to EZNEC. Guess I'll go
back to my 2x4 support system. Darn!

Why are you using a 25 ohm termination? The procedure for calibration requires a short, open, and 50 ohm load. It is also important that you know the coupler directivity at the test frequency. There is nothing wrong with calibrating the test fixture at the end of an unknown length of coax; although you will experience some degradation in the dynamic range of the return loss.

==========

Cec, I'm curious but not surprised. What are the approximate
dimensions?

Height of tower.
Length of vertical radiator.
Number and length of radials.
Any loading coils?

Your discovery of current in the tower should not be surprising. It is
just another radial.

It seems to me there should be negligible loss in the tower. There may
be a very small loss in the ground. The tower is just another
radiator. There will be some effect on the radiation pattern in the
vertical plane. It will affect the so-called take-off angle. It may be
advantageous.

Imagine what might happen if the radials were removed.

Frank,

The Smith Chart shows that a termination value other then 50 Ohms is required to calibrate the 8405a to zero phase for the frequency and cable. That said there are two zero points, I will have to think about the effect of these on the measurements.

>I'm putting a vertical back up for transmitting and will
>probably receive on my horizontal dipole.

Why? Doesn't make sense. If the vertical is best for
transmit, it should be the best for receive 98% of the time.
And visa versa.. When I ran both a dipole, and a GP,
I almost always transmitted on the antenna that I received
the best signal to whatever path I wanted to work.
If you run a good vertical for DX, and receive on the dipole
you will lose half the advantage of running the vertical
the way I see it.

>The vertical
>will be mounted on the top of a 30 foot Rohn 25G tower
>with the base grounded in cement. The question arose in
>my mind whether to connet the drooping elevated radials
>to the tower or not. Does anyone else
>worry about such things?

I don't think it matters too much as far as the operation
of the antenna. Either will work. But almost all my GP's
had the radials attached to the mounting plate, which in
turn was mounted to the mast. So all mine had the radials
connected to the top of the mast via the mounting.
Same as most any commercial ground plane...
MK

To fix a problem on a single band, you could de-tune the tower with a loop trap - a wire running alongside the tower for part of its height, with a capacitor to bring the whole thing to parallel resonance.

It's described in the antenna books by ON4UN and G6XN (and possibly also in the ARRL Antenna Handbook).

An idea,
so if one took a random length say 30 foot length of twin feed,
stuck a big 50 ohm resistor on one end and a ballun to bring it to 50 ohm
resonance at the other,
in the tuner via coax. would it be 50 ohms wide banded because it sees the
50 ohm 'dummy load' at the far end as a match, and radiates a signal 'of
sorts' from the twin feed. If one used the tuner to miss match the
'antenna' The worse the match the more signal would squirt from the feeder.

Sometimes I let them get all the way through their spiel, then I tell them that it really sounds great and that if I ever get well enough to go back to work, I might be able to buy it It really pisses them off. ;-) Other times I just tell them right away that I am 100% disabled, and in too much pain to put up with them. Of course, being on the national "Do not call list" stopped almost all of those irritating calls. The only problem I have is some deadbeat is, or has given out my phone number when they bought crap on credit. I keep a list of these calls and if I get a second call from a company I scream at them while demanding that they leave me alone, or I will have a lawyer on their ass for trying to collect someone else's debt from me.

The only ones too stupid to listen was "Countrywide" which was some kind of mortgage or lending company who had someone different call each time, from different phone numbers. They finally left a message on my answering machine with an "800" number stating that it was an emergency, but didn't identify themselves. It was their headquarters, and I really tore into them, informing them that I had repeatedly told their phone monkeys they had the wrong phone number, that I was a 100% disabled veteran, and that I was not going to put up with even one more phone call. I laughed and told them that if I did get one, that I would call friends at a TV station to have their local office investigated by their news department for violating a lot of different laws, and that I was going to turn over my hand written logs of all of their calls, along with their misleading telephone message. I asked what they thought that would do to their business in the area, just before I hung up my phone. I never heard from them again. :)

Dan,

I am not sure how you arrived at the above conclusion. The procedure should be as follows: Short the end of the coax at the antenna location, then adjust the line stretcher for a 180 degrees phase shift. This is your reference reflection coefficient of -1 (i.e. 1 < 180). Remove the short and verify the reflection coefficient is 1 < 0. Connect a known 50 ohm load, which should provide a return loss of > 30 dB. The angle of the reflection coefficient is irrelevant. If the return loss of the 50 ohm load is significantly less than 30 dB, then either your load is not very good, or you have poor coupler directivity. Attach the antenna, measure, and record, the magnitude and angle of the reflection coefficient. Repeat the procedure for all frequencies of interest. You will then be able to plot the result on the Smith Chart. At the frequencies you are working, which I believe is in the 100 to 200 MHz range, it is doubtful that the non-ideal short/load standards parasitics will effect the results significantly.

I have done such measurements countless times, although with HP VNAs, which makes the procedure far less tedious.

Hope this helps,

Frank

Is a resistor used in matching a bad thing? My intuition is that it
is, but I have no math to back up the position.

One of my current projects is to understand the matching problem for
an electrically short vertical.

Using EZNEC+, when I run the SWR function with the radiator (simulated
real ground) I get an indication of Z = R + j. If I add an inductive
load at the bottom of the radiator equal to the j value it brings the
match into a reasonable range. At this point I have not grasped the
relationship of the "R" in the equation. If I use the figure for R
equal to 10% of the XL, the match gets even better, but not 1:1. 10%
comes from the suggested estimate in the help file.

Question 1: What is this "R" thing? I started out thinking it was
series DC resistance and lower is better. My interpretation of the
EZNEC results contradict this position. More "R" seems better.

Question 2: Is this an effective method of matching a 50 ohm line to the vertical radiator?

I do understand this is a math model and it ignores radiation from the inductor.

Question 3: Looking ahead, I think the next matching technique should be an inductor in series with the ground end of the radiator and the ground. The 50 ohm line would feed a tap on the coil 50 ohms up from ground.
Do I compute XL from the bottom to equal 50 or is this strictly a cut & try thing?

I have yet to physically model anything with these tests but I am getting close to it.

I know there are better matching methods than what I am attempting, this is an academic exercise for me!

I am getting close to pulling some cable through a 1 1/4 inch PVC conduit that runs about 20 feet from the third floor attic to the basement. The contractor claims the conduit is a "straight shot" with no bends. I have three LMR240 cables with PL259 connectors on each end. And I would also like to pull a 450 ohm length of ladder line. (Measures about 1 inch.) And I would like to pull at least two 16 gage insulated control wires.

Any advice would be appreciated.

Thanks, jimbo

A Google search should get you the electrical handbooks and codes (e.g.
NEC) for the maximum fill for each conduit size. As a rough rule NEVER
fill a conduit more than 70% to 75%.

The NEC is mostly for wires for the AC lines. It will not apply for the
antenna wires.

The ladder line is not going to work too well in the conduit with the other
wire. There is a minimum distance that it should be placed from other
conductors.

I specified a similar PVC conduit when our home was built. I simply "dropped" the cables down the conduit from the attic, and let gravity do all the work. If you drop them all down together at the same time you should have no problems. The LMR240 and control wires will be fine, but ladder line in the same conduit with all those other wires probably won't work very well.

Thanks for the replies. The ladder line would be used when the other lines were not being used. Does the proximity of other unpowered lines affect the ladder line operation for receive and transmit?

Thanks, jimbo

I think you can get those three coax lines down the straight conduit
if you stagger the PL-259 connectors, however, once you have a couple
cables in the conduit, you may find there isn't enough room for a PL-259
to squeeze by, so you may need to remove the connectors, pull the cables
and then reinstall them. Three LMR240s and two control cables are going
to fill that conduit more than you realize!

As far as the Ladder line goes, DON'T ! It will be nearly useless
packed in with all that coax and wire as it needs several inches of
SPACE around it to function properly, with no nearby metal objects. That
coax braid in close proximity will drastically reduce its effectiveness.

Frank,

Your comment about my post is correct upon analysis it is not relevant.

I am trying to identify the resonance frequency of an antenna. When that point is found I am trying to measure the input impedance (should be R + 0j).

Assuming 50 Ohm source and cable, the smith chart shows for lengths of cable terminated in values other the 50 Ohms, say 25R 0j, those points will plot of a constant SWR = 2 circle. I am using that circle below:

I am assuming that for a frequency where the antenna is resonant that the phase read from the antenna and the phase read from non 50 Ohm 0j load will be the same. If that is true then 'zeroing' the meter by adjusting the phase offset will not effect the frequency of resonance. It is simply a convenience.

This method should yield a direct resonant frequency reading.

~~~~~~

Nope. Verticals are notorious for picking up local man-made noise.
Man-made noise starts out with random polarization but the horizontal
component is quickly "shorted out" by the earth's conductivity, leaving
only the vertical polarized component. This is why AM broadcast
stations universally use vertical polarization; better groundwave
coverage. They are not concerned with skywave or local noise.

For skywave, either one works fine, but a horizontal antenna is quieter.

Yes a very negative effect and not a good idea.. If you look in the history of this NG you will see some numbers about minimum separation distance from other metal.

If you really want to run a balanced feeder you can use two pieces of coax with the shields connected at each end. The Z will be twice that of the original coax. (I use this as a Q section on 20m feeding a loop of about 170 ohms) Dunno about losses in this case (which open wire feeder are great for reducing) and of course the Z is going to be kind of lower than 450r.

Jimbo,

It's going to be crowded in that conduit, so don't rely upon gravity to get that stuff down the pipe. Three suggestions:

1. Buy a 25 foot electrician's steel snake (Home Depot, Lowe's, ...), use this to pull the wires through; or drop a length of poly line/guy string as a pull line. If gravity does not get the pull string through the conduit, tie a lightweight object to the line and suck/pull with a leaf blower or vacuum cleaner.

2. Stagger the pl-259's and open cable ends as much as possible so that this looks like a pointed, rather than a blunt, object going through the conduit.

3. When you're pulling the wires into the conduit, do your best at the feed point to keep the wires "straight" and not twisting into the conduit. This takes less space and permits you to do item #4 .

3. ADD A PULL STRING IN THE CONDUIT WITH THE WIRES! So when you're all done, three months from now, and you realize you just want to add one more little 4 conductor cable (or whatever!), you can do it without completely dismantling the cables. {been there, done that}

That's certainly not true at my QTH. The vertical has two
extra S-units of noise on receive compared to my dipole.
I'm assuming the two extra S-units of noise on receive
won't affect my transmitted signal. When I had my 40m
vertical up, I never heard any signal that was better
received on the vertical. +12 dB of noise is virtually
impossible to overcome in actual practice.

Especially transmit. You will lose a lot of your transmitted
power to the conductors surrounding the ladder-line. Ladder-
line should be run a few inches away from anything.

Ralph -

I am not referring to the AC portion of the NEC, RATHER I am trying to
highlight the maximum fill (diameter of each cable and maximum pull).
ever try to "pull conductors" through conduit when this rule is NOT followed
??

I have, it's pain .. in the xxxx.
Easy read and math calculations are minimal with tables supplied --- number
of conductors and O.D. versus the I.D. on conduit.

If you get two extra units of noise, but the signal comes up
four.... Well, you get it... I didn't get much extra noise going
vertical at this location. The stronger signals always overrode
it. The noise should be a non issue in most cases.
But this also leads to an important question. Do you actually
work long haul paths? If you don't , you probably won't see
much advantage to a vertical. If you listened to long haul dx
paths, and the vertical never beat the dipole, you didn't have
a very good vertical. Actually, I've already pondered on that
in the past. Yours was pretty low, with not many radials
the last time around. The combo of mediocre antenna, and
not using it for long paths is why yours was never better
than the dipole. If I remember right, you weren't even talking
over 1000 miles most times.

I disagree. Transmission lines have two conductors. Radials don't. The fields from transmission lines are confined to the region between the conductors. The fields from radials can couple quite strongly, altering their performance a great deal. It might be possible to model a radial system as a system of coupled transmission lines. Is that what your program does?

I have the same tuner. Are the antennas really grounded when in dummy
load position? Looking at the circuit diagram, I can see the coax
braid is always grounded, and one side of the balanced line is always
grounded. But are both sides of all antennas grounded when in the
dummy load position? From what I can see, the coax center conductors,
and one side of the balanced line are left floating.

This is why AM broadcast stations universally use vertical polarization; better groundwave coverage. They are not concerned with skywave or local noise.

>For skywave, either one works fine, but a horizontal antenna is quieter.

They don't pick up *that* much more noise. Sometimes the difference would be fairly small. When I ran both the elevated GP, and the dipole,
the antenna that received best, transmitted best nearly all the time. If there were exceptions, they were so rare as not to really remember them. If you are working long haul DX paths, the signal increase of the vertical will override any extra noise. And the increase is almost always higher than the increase of noise. Noise on the vertical was never really an issue here. And I'm in the big city of Houston to boot. When I talked to VK land using both antennas, the vertical would beat the dipole by appx four S units. Both transmit and receive. If the noise
came up an S unit or two, it's a non issue. When working from here to the west coast, ditto, except the difference would be two S units instead of four. Even in those cases, the noise was never high enough to make the dipole the preferred receive antenna. Dunno..I think all this "noisy on a vertical" talk is greatly overstated. Also consider that most of my local noise here is random, and often effects both antennas nearly equally. If you are working long DX and receive on a low dipole, you could be robbing yourself of a lot of received signal to be had. In my case, 4 S units worth to any long haul dx. You telling me I'm gonna see 4 S units of extra noise? Never here at this QTH... Maybe 1 or 2 at best. I *never* wanted to receive on my dipole if I was working long haul off the vertical. Would be like shooting myself in the foot.

Let's suppose that your antenna was a black box instead of an antenna. You connect a source to it and look at the impedance looking into the black box. If the resistive part of the impedance (the R) was zero, the box would contain the equivalent of only an inductor (if the X was positive) or a capacitor (if the X was negative). Although you would measure voltage and current at the box's terminals, you'd find that they were 90 degrees out of phase with each other, and no power would be delivered from the source or consumed by the box. Not the situation you want with an antenna -- you need to deliver power to it so that power can be radiated.

If, on the other hand, you see some R when you look into the box, you can calculate that the power being delivered by the source and consumed by the box is I^2 * R, where I is the RMS current at the box terminals.

So R is always present at an antenna feedpoint at any time the antenna is radiating power, since part of the power "consumed" by the antenna goes toward radiation. This R is called the "radiation resistance". Some part of the power supplied by the source is also actually consumed by heating the wire and ground. This increases the R seen at the feedpoint. That part of the total R is called the "loss resistance".

What you want to do is to maximize the fraction of the power that's radiated, and minimize the fraction that's wasted as heat. So you want to make the ratio of radiation to loss resistance as large as possible.

If you have a short antenna, you'll find you can raise the radiation resistance by lengthening it or adding a top hat. Center loading with a coil also raises the radiation resistance, but you can end up increasing the loss just as much due to coil resistance.

With EZNEC, you can set all losses to zero by setting wire loss and the loss of all loads to zero and, if using a grounded vertical, using MININEC type ground. Then the R you see is only the radiation resistance, and the field strength is that of a 100% efficient antenna. Reintroduce the losses and you'll see the loss resistance added to the radiation resistance at the feedpoint. The field strength will drop according to the reduction in efficiency.

> Question 2: Is this an effective method of matching a 50 ohm line to
> the vertical radiator?

Any resistance you intentionally add will increase the loss resistance without changing the radiation resistance. More of your rig's power will be spent heating the resistor and less will be radiated. In some instances, such as military frequency-hopping applications, the trade of greater bandwidth for less efficiency might be worthwhile. You'll have to decide for yourself whether it is for you. There are certainly a host of other matching methods which are less lossy, but few which can achieve the extreme broadbanded match of a resistor. But don't be fooled into thinking that because the match is broadbanded that you're radiating the same amount of power over the band. The wider the bandwidth, the larger the fraction of your power you'll dissipate in the resistor.

> I do understand this is a math model and it ignores radiation from the
> inductor.

"Loads" don't radiate. Inductors modeled as wires using the helix creation feature do.

> Question 3: Looking ahead, I think the next matching technique should
> be an inductor in series with the ground end of the radiator and the
> ground. The 50 ohm line would feed a tap on the coil 50 ohms up from
> ground.

That's not likely to work.

> Do I compute XL from the bottom to equal 50 or is this strictly a cut
> & try thing?

You don't want an XL of 50, you want the feedline to see an R of 50 with no X, that is, 50 + j0.

> I have yet to physically model anything with these tests but I am
> getting close to it.
>
> I know there are better matching methods than what I am attempting,
> this is an academic exercise for me!

Look into making an L network. It would be a good opportunity to learn how to use the Smith chart, and you'd end up with a low loss matching solution.

This question does not fit perfectly into any rec.radio.amateur newsgroup so I'll cross-post it to three groups and hope someone can help me.

The question involves the dangers of RF energy from HF, VHF, and UHF rigs around automobile electronics.

I am installing a Yaesu FT-857D in a 1997 Mazda B4000 truck -- 4.0L V6, 4WD, 5-speed, with extended cab.

The control head for the 857 is separated and mounted on the plastic bezel around the gear shift lever. The rig is mounted on the floor under the driver's seat.

Underneath the truck, on the rocker panel just beneath the seatbelt anchor point, is a factory-made hole in the floor. This hole is closed with a removable rubber plug. I ran the radio's power lead through this rubber plug, along the frame, into the engine compartment where I attached the positive lead to the battery and the negative lead to chassis ground.

I planned to run the antenna leads out through the same hole then run them along the frame into the sidewall of the bed to the rear of the truck where I will mount a VHF/UHF antenna in one rear stake hole and an ATAS-120 in the other rear stake hole, using the GeoTools mount:
http://www.geotool.com/antmount.htm

I took the truck in for service last week and the service advisor gave me a long lecture about keeping the coax away from the air bag and away from the seatbelt retractor. He told me the retractor has a small explosive charge in it that can be set off by radiation from coax. Ditto for the airbag.

The route I planned for the coax takes it right next to the seatbelt retractor and I am now re-thinking my installation. I could route the coax from underneath the driver's seat directly to the back of the cab and drill a hole in the floorboard, centered on the cab at the back wall of the cab, and run the coax out of that hole. This would get a foot or more separation between the coax and the retractor.

I plan to ground the hell out of this installation.
-- The power lead is grounded to the frame in the engine compartment.
-- I have a 10 gauge pigtail -- one end will be bolted under one of the bolts that attaches the seat frame to the floorboard and the other end will be bolted to the 857 chassis.
-- The antenna mounts bolt directly onto the chassis; I will sand off the paint and use star washers to get good contacts at these mounting points.

Also, I will use double-shielded RG-8X for the coax.

I see a lot of trucks like mine (the B4000 is the same truck as the Ford Ranger) with CB installations -- I have never stopped anyone and asked but it seems to me the normal CB installation is nowhere near as good as mine and they don't seem to have problems. Of course, I'm running 100 watts and they are running only 5 (right???).

Has anyone out there had experience with HF mobile installations in the Mazda or Ranger pickups?

Thanks for your assistance.

775. Help with J antenna design

Plan is to build a J antenna for 20 meters using 1 inch EMT conduit. Antenna will be supported at the bottom by a 4x4 post in the ground and at the 30+ foot level with a fiberglass bracket bolted to the eve of the house. The upper most section will be a fiberglass 1/2 wl antenna thta used to be used for CB. I am looking for a program that will allow me to calculate deminsions for a project like this. Feedline will be 50 ohm coax.

Dan, The reflection coefficient of 25 ohms is 0.333 <180, so if you do trim the line stretcher for 180 degrees, then attaching the antenna will determine how close you are to nominal R + j0. You need to reset your line stretcher at each frequency until you obtain a 180 degree phase shift on the return loss from the antenna. It is reasonable to assume that your antenna has an impedance in the region of 37 ohms, so the 180 phase shift is probably correct. For the reflection coefficient at 0.333 < 0 the input impedance is 100 ohms. For such an antenna it is probably easer to just tune the antenna for minimum reflection coefficient and forget the phase angle.

what are Microwave Antennas?

its wire or steel rod antenna, with a nice sharp point that is long and thin enough, that you can thread your sausages on, you then power up the radio/antenna, and the bangers will cook nicely. Discovered by 'wireless ops using the VHF section of the WW2 WS number 19 Mk 3.

The vertical was 2 S-units noiser than the dipole. There's no
evidence that, with the same height limits, a monopole vertical
could ever beat a dipole's broadside performance by 12 dB at
any angle.

Yes, I have. I work at a large industral plant. Some of the wire I have pulled has been in 1 inch conduit that was probably 90% full of # 12 wire already. Still needed to get another pair of wires through that. I have cut a couple of wires in the conduit and used them to pull in wire to replace them and two new wires. No room in the conduit to push a snake through and pull the new wire in. Use lots of the wire pulling grease. Most of the wires are control wires and only have about an amp or less on them. We are not worried about overheating the wires in the conduit, but need to add new control circuits to a 40 year old plant. As you said it is a pain.

Sounds like your dipole was not a very good dipole. With
the same height limitation, EZNEC says the vertical will
NEVER be 4 S-units (24 dB) better than the dipole's broadside
performance at any angle.

At http://www.qsl.net/w5dxp/dipvsver.htm is a comparison
of my 130 ft. dipole at 40 ft. with my 33 ft. vertical
with the feedpoint at 20 ft, both on 40m. There's only a
tiny sliver where the vertical beats the dipole broadside
and isn't even close to 24 dB.

You don't need a program. The long element is 3/4 wavelength long. The
shorter parallel element is 1/4 wavelength long. You can short the
two elements together at the bottom and attach your feedline at the
50 ohm point on the two parallel elements. Or you can feed the long
element with the center conductor and the short element with the
braid of the coax. 3/4 wavelength on 20m is about 50 ft.

The free demo version of EZNEC from www.eznec.com will probably model
that antenna.

You ought to think the hell out of your grounding plans first.

Remember, "grounding" simply provides a current path that did not exist before. This can be good or it can be bad. Know what current is flowing and where and why. "Grounding" stuff willy-nilly is not good engineering. Make the current go where *you* want it to go or not go.

It sounds to me like the only issue you might have is the coax running near that seatbelt retractor. The thing that puzzles me is this guy telling you there is a small explosive charge in the seatbelt retractor. I never heard of such thing in my 30+ years of doing radio installations. I would like to hear from anyone else here who has! I sure have no idea what the purpose of this charge would be.

They are the latest things, called "pre-tensioners" they fire along with
the airbags. I would think that routing the coax as far away as possible
and making sure the radio and the antenna base (and antenna end of coax
shield) are securely grounded would be sufficient.

He should carefully check all options to see if their is a way to avoid
most of the wiring loom in the vehicle.

The use of the stake mounts, concerns me because they might not ensure
mettalic grounding of the antenna. I would make sure the antenna is
grounded to the truck bed and the truck bed to the vehicle frame by
short <1/8 wavelength wires.

I am assuming the reflection angle of 0j terminations would all be the same (you said <180), this includes both resistive loads and an antenna at resonance. The method I am using relies on that.

I am confused about one thing in the smith chart program. Cables identified as stubs create a circle that goes through infinity and do not exhibit a constant SWR, while simple cables create a constant SWR circle with the center and 50 Ohm 0j.

I believe the setup I am testing exhibits the constant SWR characteristic.

Ha ha ha .. well we did follow up work behind the same guy !! :-)

Sadly, the grease did not help in one of my situations with 3/4" conduit ..
had to finally tear out of wall and then replace with 2 conduits for the
wire runs.

No real-world transmission line exhibits a constant SWR since
no real-world transmission line is lossless. Constant SWR
circles are approximations. The actual SWR curve is a spiral
from a point on that constant SWR circle that, in the limit,
spirals down to the Z0 of the line.

For instance, using Owen's feedline calculator, the SWR at a
500 ohm antenna fed with 100 feet of RG-58A is 10:1 and the
SWR at the other (source) end is 1.42:1 for 146 MHz.

just a question. what would the antenna get you that you don't already have
with the HT antenna when used on a bicycle? (aside from loss in the coax
cable)

if it was tall enough i guess you could put an orange flag on it :)

Dan, if the load is resistive, and less than 50 ohms (assuming the center of the Smith Chart is considered to be 50 ohms), then the angle of the reflection coefficient is 180 degrees. If the load is resistive, and greater than 50 ohms, then the reflection coefficient angle is 0 degrees. As you approach the center of the Smith Chart the angle becomes less and less relevant.

Shunt stubs - either open or shorted - always pass through "zero" (And infinity - which you will not see since it is in parallel with the load impedance) and the selected impedance on the Smith Chart. This is based on the effect that an open stub, at quarter wave multiples, will exhibit successive open and short circuits; as will a shorted stub.

Your method will exhibit a constant reflection coefficient circle (and VSWR), with the angle varying from 180 degrees through zero degrees and then back, through negative angles, to 180 degrees.

Frank

Frank, this is consistent with what I am observing. The claim is for a given frequency when a 0j load (in the range of 10 to 40 Ohms) and an unknown load (assumed to be in the range of 10 to 40 Ohms) show the same phase shift then the unknown is 0j also. It is not necessary that the loads be the same value, only within the range. (I will have to experiment with loads over 60.)

So far nothing has surfaced to contradict this.

Thanks - Dan

Thanks Cecil, I was concerned about spacing of the stub more than anything else. I guesstimated this should be about a foot. I also know I could be totally wrong. By looking at some plans the distance between the short and long tubes seems to vary with the frequency and size of the tube. Doubt if it is too critical. I downloaded EZNEC a few years ago and could never figure out how to use it.

Thanks Richard, I have read the document quickly overall, and a bit
more detailed in some key areas.

It covers similar material to documents I collected when studying
power earthing and lighting protections in years past, but it is a bit
more comprehensive... so a good read and a good reference document.

One good pickup was the functions for predicting the low frequency
resistance of shallow buried radials (which is relevant when radial
wires are required to provide a level of power / lightning protection.
I created a graph to add to an existing web page from the functions
for 3mm (bare) wires buried 0.1m, the graph is at
http://www.vk1od.net/post/earth02a.gif . (For avoidance of doubt, this
graph does not predicting the RF characteristics of the radials.)

Tks...

Owen

PS apologies for the delay in responding, I have been up to the big

_____

For those using buried radials as one terminal of a vertical monopole...

The only path consisting of physical conductors that can exist between a series-fed vertical monopole and buried, uninsulated radials is through the PA output, and the antenna matching network at the tower base. This is not adequate to control/prevent system damage from lightning.

Three added techniques are used in most MW broadcast applications:

1. A "static drain choke" is installed between the tower base and the junction of the radials.

2. An arc gap is installed across the base insulator and set to flash over at some margin above normal peak voltage

3. The tx contains r-f phase sensors that kill tx output for a few milliseconds after an arc is sensed, so as not to sustain it.

Hello:

Don't have a good feeling for the significance of this:

For a receive only application, using coax from the Balun of a simple
outside antenna to the receiver,
is a loss of, e.g., 2.5 db "meaningful" ?

Specifics would be 100 feet of RG 58 at 30 MHz

Or is it worth the extra $ to go to a less lossy coax (application would
always be for receive only)

BTW: R/S Coax a decent quality ?

Thanks,
B.

The answer is, maybe. If the signal level of the stations you wish to hear
are strong, then -2.5db will not mean anything as receivers have a lot of
gain, but if the signals are weak then -2.5db can mean the difference
between hearing or not hearing a signal. Be aware that the loss figures for
coax are for a matched system, that is 50 ohms in/out. If the load is not 50
ohms, then the loss of the cable will be higher and the worse the miss match
the higher the excess loss will be. It can be allot. I've seen for severe
miss match excess loss of up to 20db.
As for R/S coax is not known for being of high quality nor is it consistent
in its quality.

Why not build an end fed 1/2 wave antenna and forget about the mechanics of
the 1/4 wave matching section and the problems of its height? IMHO, a simple
L or Pi network in a WX proof box with a 33' vertical would be a lot easier
to construct and adjust than a 50' tall antenna.

Robert/Bob

In a receive application it is only important that the signal you want to hear exceeds the level of total system noise by a desired amount. In your case atmospheric noise is likely to be far above that of whatever the receiver front end contributes.

Having said that my HF/6m TXCVR has a preamp that can be used on 10M with a slight useful effect. I'd suspect that this is a design problem as the same model w/out 6m doesnt have it.

My answer is no, the 2.5dB can be ignored. You may want to consider though how you should site/feed the antenna to obtain a good s/n ratio from the desired signals.

I personally wouldnt touch RS coax but I have no evidence to back up my thought that it is technically inferior. Just that they tend to buy things cheap and there is a lot of rubbishy coax around. I might go to the "Wireman" or direct to a well known manufacturers (Belden S&H etc) retailer.

Cheers Bob VK2YQA

The last time I bought Radio Shack coax cable, the shield was so
thinly populated with wire, it was almost nonexistant.

You might try some of your local computer stores that deal with
networking installations. They frequently carry good quality coax with
brand names like Beldon. (One of my local computer stores has Beldon
RG-58U at 22 cents a foot.)

Good mail order places for coax would include Davis RF, The Wireman,
RadioWorks, Amateur Electronic Supply, HRO, etc...

I use the through hole in the floor of my Ranger [Ford] as you describe.

Coax should have no rf current on the outside of the cable assuming a
good ground at the antenna.

This is a series of questions about AM broadcast antenna and lead-in problems I have, it is not a strictly "amateur radio" question, so I hope you forgive the intrusion but I thought this group to be the best for the question.
I have purchased a Russound ST2 dual tuner for medium wave (AM broadcast) and FM for my whole house audio system. I have hooked up a Radio Shack FM Stereo Antenna in the attic and it works well for FM. The AM antenna input is 300 ohm. Two loop antennas (about 5" diameter) are supplied but do not work well in the room I have the tuner as there is lots of noise and weak signal. I would like to mount the supplied loop antenna(s) in the attic. I am 18 miles from New York and only want to recieve local broadcasts (no DX). It is not practical for me to put up a 200 foot longwire. I have to make some decisions:
1. Can one antenna feed both tuners by being hooked up in parallell? Is there a signal loss?
2. Am I better off using 300 ohm flat TV type cable or should I use two 300/75 transformers (one at the reciever and one at the loop antenna) with RG-6 quad shield? I am wondering if the transformer loss is worth the possible noise reduction from the coax.
3. Should I be able to use 1 loop for the two tuners and the coax, is it best to split the 75 ohm coax and use independent 300 ohm transformers or to split the 300 ohm feed from one tuner to the other?
4. Is it possible to use the FM antenna for the AM and how would it be best to split that up? (I would have to feed two FM and two AM tuners but only two could be used at once).

Thanks,
Eric

The bottom 1/4WL is a quarter-wave matching stub, either open
or shorted. If it is open, you have a Zepp antenna, and they
used to use open-wire transmission line for that. One foot
spacing may be a little much. Rule of thumb - 1% of a wavelength
would be about eight inches on 20m.

Modern receivers have such a wide dynamic range that 2.5 dB
of loss on a received signal is usually of no consequence
at HF frequencies. Some hams don't even worry about that
amount of signal loss on transmit, ~ half an S-unit.

==

Owen, I assume the curves in your graphs have been obtained by
treating the conductors as transmission lines. As far as I am aware
there's no other way of doing it. Except perhaps EZNEC
number-crunching mathematical modelling methods.

At VLF the inductance of the conductors and the capacitance due to
relatively high permittivity of the dielectic material (soil) can be
neglected.

This leaves only conductor resistance and conductance (or resistivity)
of the soil. It is then quite simple for single wires.

To predict performance at RF it is necessary to take inductance and
capacitance into account. What is unknown is the way in which soil
permittivity and resistivity change with frequency. But this hardly
matters as the uncertainty at 60 Hz is sufficient to swamp it.

I won't ask you what you did about calculating the effects of multiple
radial wires, and the interaction between individual wires, which
causes "The Law of Diminishing Returns" to be followed.

There is sufficient information in your graph to demonstrate that
Magician Marzipan's magic high number of 120 is never necessary for
amateur purposes.

~~~~~~

Nonsense.

Current on the outside of the coax is caused by imbalance in the
antenna. A good ground will not get rid of it, in fact it may well be
the cause if the ground has a different impedance than the antenna.

~~~~~~

The answer depends on the noise figure of your receiver. Most modern receivers have very low internal noise and will work fine under the conditions you describe. Older receivers, especially tube sets, generate so much internal noise that it may be stronger than the signal you are trying to receive and the 2.5 dB loss will render the signal inaudible.

In other words, it depends. :-)

I am somewhat surprised at the effect of a grounded
conductive mast upon the feedpoint impedance predicted
by EZNEC. On 40m, with the radials attached to the mast,
the feedpoint impedance is 7.8 - j255. With the radials
not attached to the mast the feedpoint impedance is
81 - j219. With no radials and using the mast as a
counterpoise, the feedpoint impedance is 2044 + j1461.

Hi Owen,

Does this discount the proximity of the radials nearest the center?
That is, the graph is not simply a summation of the individual
lengths, is it?

What would nominal be (in other words, actual) for this specific
description above?

Most AM radios use a ferrite loopstick antenna. But that is part of the
input high-Q tuned circuit. Just connecting a loopstick to the 300 ohm input
of your receiver would probably not work well, but if you could put a
"source-follower" (a special transistor circuit that has a very high input
impedance and low output impedance) between a remote loopstick tuned circuit
and your set, and somehow using a voltage-variable capacitor to remotely
tune it, the result could be quite good.

A loopstick is very directional, and if pointed the wrong way, will partially null out the signal you want. However the null is directionally fairly sharp, so most loopstick antennas turn out to be adequate. In any event, AM broadcast in any but a high signal strength area with the equipment you describe is going to be "iffy", and at worst, a bother having to re-tune a remote antenna each time you change stations.

What's your experience with regular AM transistor radios around the house? Do they work okay? If they do, it suggests the signal strengths on the stations you like are probably high enough, but your choice of a radio that doesn't have a tuned loopstick antenna is somewhat ill advised. If you can take it back or sell it - - and get a better radio that has enough front end gain to use the 5" diameter loops or that has a large ferrite rod antenna on the outside that you can see - - that might be best.

Always listen to a radio before buying it, and make sure you can take it back if it doesn't work out in your system.

Good luck,

Chuck

Chuck,
Thank you for your detailed reply.
I have to use this tuner as it is part of a whole house audio system that is remote controlled. As such, I can't simply swap it out with another set. All of the stations I need are in the same place, New York City, so I won't need to reorient the loop once it is set. All I am looking to do is place the same antenna in the attic, and I need some advice on the connections.
Thanks,
Eric

Sounds like your dipole was not a very good dipole...

A dipole is a dipole. You can't go by what eznec says.
My modeling didn't match my real world either unless I
cranked the ground quality up in the modeling program.
My GP was *always* about 4 s units louder than the
dipole to VK. Every time I compared. I had a regular
sked over there 3 times a week. The GP was
always 2 S units louder to the west coast than the
dipole. Every time I checked. The dipole was at
36 ft. The base of the GP was at 36 ft. There are
factors in comparing the two antennas in the real
world, that I don't think modeling takes full account of.
Also, my ground is better than yours too. My GP was
higher than your last one by nearly double. Don't
confuse what you saw with your last one, with what I
saw on mine. Mine was a good bit more efficient as
far as radial number vs height in wavelength vs the one
you ran last time.
Of course, S meter readings mean zip as far as actual
db improvement, but there is no doubt my GP smoked
my dipole on long paths. Day and night...And the difference
was reciprical xmit/rcve in almost all cases.

>Suit yourself, but any serious DXer will tell you there are times when
>one dB of S/N ratio would make the difference between QSO and no QSO

Sure, but the actual signal level increase on a long path is
almost always stronger than any increase in noise. I never
once felt the need to use my dipole for receive in place of the
GP. Would be stepping backwards. Now, on the low bands
like 80/160, a beverage, etc, might be better for rcve, but I don't
use those on 40m.

I have 2 units of Satellite TV Antennas

Both were used and removed from service.

One is a 22 inch Dish 500 antenna with 2 LNB's on it. LNB's look good.. cover around them is cracked. Antenna has MAST mount. Complete antenna is in good looking shape, $50

Second is 19 or 20 inch Direct TV antenna,, NO LNB.. mount is there and a mount for a mast.. $25

I have (2) 9 inch Panasonic WV 5370A monitors, These are 9 inch professional grade (so I am being told.) Video monitors. THEY are in good looking shape. WITH very very heavy brackets to hang these monitors up. I did plug them in. AND I get NO power lite. I don't know if I have to feed them video to have them come on. SO I am selling them AS is. THEY could be perfect. I am not sure. If not this is good equipment so its worth repairing. $50 ea

Scientific Atlanta Cable channel 18 video Modulator.. Works well.

$100.. (I have a picture of this)

NO pictures of the other stuff.

SHIPPING not included ,,

>1. Can one antenna feed both tuners by being hooked up in parallell? Is
>there a signal loss?

Hi Eric,

Yes/Yes. Does the loss matter at a distance of 18 miles? Probably
not. However, this question is rather hazy given the ones that follow
seem to ask the same thing again.

>2. Am I better off using 300 ohm flat TV type cable or should I use two
>300/75 transformers (one at the reciever and one at the loop antenna) with
>RG-6 quad shield? I am wondering if the transformer loss is worth the
>possible noise reduction from the coax.

Again, the presumption of loss is exaggerated. Your problem, as you
describe it, is noise. However, the transformers are probably more
suited for FM than AM. On further consideration, that may not matter
either as it is the shielding action of the coax that may in fact
offer more payback in noise reduction for the AM operation than any
issue over the expected transformer loss.

To take this one step further, at the AM antenna end of the coax,
simply coil the coax around an empty liter coke bottle with a dozen or
so turns. This is more to help isolate from noise than anything else.

>3. Should I be able to use 1 loop for the two tuners and the coax, is it
>best to split the 75 ohm coax and use independent 300 ohm transformers or to
>split the 300 ohm feed from one tuner to the other?

Another hazy question. Run separate lines for AM and FM. You can
combine them, and split them out at each end so that there is only one
long run of coax (which is commendable). However, as you are
approaching this with a known problem, it is in your best interest to
keep the bands/antennas/lines separate.

>4. Is it possible to use the FM antenna for the AM and how would it be best
>to split that up? (I would have to feed two FM and two AM tuners but only
>two could be used at once).

Another hazy question. Through all this haze, it seems you are quite
set upon combining things. With such a wide separation in frequency,
you would tend to end up with a single solution that poorly serves two
purposes. It raises the complexity factor, and any problem compounds
that further.

This simply means that, yes, you can; but it would not seem likely you are actually doing yourself a favor.

I'm going to buy a rotor for my flag antenna. I have a rotor now but it is
one of the old TV antenna rotors with a control unit that goes klunk, klunk,
klunk,
as the antenna turns. I'm hope newer rotors have quiet control units.
It doesn't have to be heavy duty the TV antenna rotor has worked fine.
What are some rotor suggestions?

P.S. Has anyone built a quiet control unit for the old Alliance U-110 rotor?
My rotor works fine, but the klunking at midnight bothers my wife!

Richard,
Thanks for your detailed answer.
I am not really set upon combining. I am glad to run another wire. I gather from your response I am better off with the coax and two transformer setup than with using 300 ohm twin wire for the strictly AM radio purpose.
Thanks,
Eric

At 30 MHz, you're right at the border between HF and VHF. Below about 30 MHz, atmospheric noise dominates, and reducing the coax loss will make no difference at all in your ability to hear signals. Above about 30 MHz, receiver noise dominates, and reducing the coax loss 2.5 dB will make an improvement, the amount depending on the relationship between the receiver noise figure and the atmospheric noise. But the boundary is fuzzy, so right at 30 MHz it's probably a toss.

But here's a very simple test you can do which will give you a definitive answer: Tune the receiver to a frequency where there's no signal, and disable the squelch if it has one so you can hear the noise. Then disconnect the antenna from the receiver. (With some receivers you might have to replace the antenna with a dummy load rather than just disconnecting it, but that isn't usually necessary.) If the noise level drops when you disconnect the antenna, reducing coax loss or otherwise improving antenna efficiency won't make any difference in your ability to hear signals. If the noise doesn't drop, then efficiency improvements will improve your ability to hear signals.

Hi Eric

I certainly welcome your question, amateur radio related or not!

Most effort in amateur radio circles on MF is associated with matching a transmitter and antenna. The next most important step is to increase the desired signal to noise ratio into the receiver (by using antenna directivity, type and orientation etc) Since atmospheric noise is far stronger than that contributed by the receiver device, actual signal loss over the feedline length isnt normally an issue. The actual signal level isnt important provided it is greater than the noise.

1. Under perfect conditions assuming known source, load and feedline impedences, yes the power going to each receiver will be cut by half (3dB). Purist may argue that a simple "in parallel" configuration is a bad thing. For AM MF I dont think you'll even notice it...

2. I doubt the balun to RG6 would be useful. I'd also suspect they will be hard to find given the operating frequency. (Cheapo TV baluns probably wont work well much below 40MHz) One of the problems you will encounter coax or ribbon is that if the antenna isnt symmetrical you will receive noise from along the length of the feedline itself. Not a good thing if it runs past a fluro or light dimmer (or wiring).

I also doubt that the input Z at the antenna input terminal truly is 300 ohms. I mean it works over a 3:1 frequency range as well..

One of the downsides of using ribbon is possible interactions with nearby metalwork. I'd suggest in your case that it wont be an issue. In fact using the supplied loop antenna may be no better than using a random length of wire (dipole arrangement) attached to the ends of the ribbon in the attic. The line loss is not so much an issue than the signal received at the antenna itself.

I'd suggest you use the random wire approach with the ribbon in parallel to both tuners and see what the signal is like. If it is still noisy play with the antenna polarity (vert vs horiz or at least diagonal) I suggest that trying to match impedence and getting the same signal power in each line/RX isnt important at all. If one wanted a perfect configuration (ie for transmitting) the difficulty is major given the frequency range the thing has to work over.

Tell us how you fair

Cheers Bob W5/VK2YQA East Texas

Hi, Eric,

I was just looking at the specs of the Russound ST2, and it doesn't look too good for AM reception. 55dBu sensitivity is really, really poor - - that's 562 microvolts to reach 20dB signal/noise ratio - - no wonder the loops don't work well on stations 18 miles away. Typical AM broadcast sensitivity of Ham Radio gear runs around 13 microvolts. I think you can forget about AM broadcast, especially if you have one with XM radio, since XM will most likely occupy more of your listening time. It looks to me like the manufacturer is just not serious about providing any decent AM reception. The 3 KHz response on AM is also not very inspiring - - maybe okay for news or talk radio, but not much more. If anything can improve the outlook on AM reception with this radio, here's a website that may help: http://www.mindspring.com/~loop_antenna/

Good luck,

Chuck

Hi Eric,

Why you would use 300 Ohm twin wire for AM antennas is odd, but not prohibited. However, it does demand all the attention to keeping the line balanced (like I said, move away from coax, and problems become compounded). If there are 300 Ohm issues both at the antenna and at the radio, you must preserve them through transformers if you do migrate to coax.

Balanced goes by many requirements, none of which can be ignored. An unbalanced condition is a tacit allowance for the intrusion of noise. As you describe a problem with noise - well, you see where this leads, an absolute exercise in driving out the imbalance.

Where does it occur? How do you find it? The problems are stacking up already. It happens at the antenna itself when it is mounted near conductive materials. This observation only leads to more questions, what might be conductive that is nearby, and how near is nearby? The same problem exists with coax feeds, but you can solve those easier with the coiled lead at the end (you probably could do the same with twin lead - and winding either lead 4 or 5 times through a ferrite core could be equivalent fixes). However, this is only at the antenna end, and that may not be the source of the imbalance. For twin leads, it could be as easily that the lead traces up against metal ducting, or along house wiring.

If you are scrupulous about these kind of details, twin lead may indeed work fine.

Another method of tackling the problem is to carry a small transistor radio around the house, and try to locate the noise itself. Killing the source is a one pound cure for a ten pound problem. If the noise comes from outside the house, then you have antenna issues, and all the wishing in the world in trying to avoid a different antenna will come to naught.

Let me quote again:
< (For avoidance of doubt, this
> graph does not predict the RF characteristics of the radials.)

The graph uses the functions in the paper identified by Richard (
http://www.usda.gov/rus/telecom/publications/pdf_files/1751f802.pdf
). Looking at the functions, I think they just calculates the DC /
low frequency resistance of the electrodes immersed in the soil which
is a high resistivity medium, by modelling the geometry of the
equipotential "layers" around the electrode as is done with a single
straight earth electrode. The functions for 6+ radials (or all of
them) may just be a fit to experimental data.

>
>At VLF the inductance of the conductors and the capacitance due to
>relatively high permittivity of the dielectic material (soil) can be
>neglected.

I think these functions are for the resistance at power frequencies
(ELF?) and are not applicable to RF. Nevertheless, most lightning
protection texts seem to deal with the earth system as a DC resistance
with some lumped series inductance to model the above ground
connection, though clearly, lightning spikes are a double exponential
with components up to VHF depending on the way in which the network
modifies the waveshape.

See above.

>
>There is sufficient information in your graph to demonstrate that
>Magician Marzipan's magic high number of 120 is never necessary for
>amateur purposes.

I am guessing that the magic 120 was from BLE's paper, and it was
talking about performance at 1MHz or so, so it is RF performance that
is being considered.

The graphs I produced certainly suggest that at DC / 50Hz / 60Hz, that
there is insignificant benefit in installing more than 6 or 8 radial
wires. The reasons will be the same as why installing two vertical
electrodes close together achieves almost no improvement.

nm5k@wt.net wrote:
> The dipole was at 36 ft. The base of the GP was at 36 ft.

Well, there's the problem. You stopped your dipole where
your vertical started so any comparisons are bogus. Your
dipole was an NVIS antenna. :-) It's not a fair comparison
since the vertical was given a 2x height advantage. (That's
like putting my three foot six inch grandson up against
Shaquelle O'Neal in basketball. :-) Put the dipole at 70
feet, like the vertical was, and see what happens.

The top of my vertical was at 53 ft. and my dipole was
one of its upper guy wires at about 50 feet so the two
heights were essentially opposite yours.

Which brings up another question. If the top of a vertical
is at a certain height, what height of dipole would be a fair
comparison? It is certainly unfair to compare feedpoints
at the same height, like you did. It may also be slightly
unfair to compare them at the same maximum heights, like I did.
It seems a fair comparison might be made when half the vertical
is lower than the dipole and half is higher than the dipole,
i.e. the height of the dipole is at the midpoint of the
monopole?

Richard,

See my response to Reg.

The functions are from the reference paper you identified. I don't
recall that they explained the derivation of the functions, and they
may even be fits to experimental data. They do not appear to do
something as crude as summing the individual lengths.

>
>What would nominal be (in other words, actual) for this specific
>description above?

Did you mean "normalised"? You need to multiply the %/m value from the
Y axis by the actual soil resistivity in ohm-metres to get the
resistance of the electrode. For example, if you look the chart up for
3 radials of 5m length, you get 15%, which is multiplied by soil
resistivity (say 50 ohm-metres at a location) to get expected
electrode system "DC/AC" resistance of 7.5 ohms. (The graph is part of
a larger article which explains my "normalisation".)

Interestingly, I note the ref doc recommends galvanised electrodes. I
have been conducting an experiment here where I have recorded the
resistance of several driven earth electrodes over some years, and a
galvanised electrode of 25mm OD performs much worse than a copper clad
electrode of 13mm OD driven just 300mm away from it (both 2.4m long).
(The galvanised electrode is not electrically bonded to the earth
system for reasons of galvanic corrosion).

Don't forget the single-conductor transmission line invented by Goubau
and named "G-Line" in his honor. Quoting from page 164 of my 1972 copy
of "The Radio Amateur's VHF Manual":

"The basic idea is that a single conductor can be an almost loseless
transmisison line at untra-high frequencies, if a suitable launching
device is used. A similar launcher is placed at the other end.
Basically the launcher is a cone-shaped device which is a flared
extension of the coaxial feedline...."

>Hi Owen,
>
>What method did you use to measure the resistance?

I used a Kyoritsu instrument designed for the purpose. It uses the
three wire fall of potential method, and makes its measurements using
an AC waveform of about 800Hz.

having lost the support on my 6m beam and haing a turner able to tune a random wire I have decided totry it

since i don't know I will like it id rather avoid cutting this nice piece of wire

thinking about unwiding some wire from a 1/2 mile spool anythoungts on howmuch and what happens if I don't cut it off the spool(just unwind 10ft fifty or whatever leaving one large inducer on the end of the "antenna

While the lumped element match is a viable solution. Here's some info (I don't see Cecil's response)

The spacing of the ~1/4 wave matching section is not critical - here's why. First, it can be viewed as nothing more than a section of transmission line, obviously shorted at the bottom (though this section does not have to be vertical, it's just convenient in many cases).
The spacing and thickness of the conductors will determine the characteristic impedance (Z0). Normally the Z0 of T-Line is critical, but this is a bit of a different situation. You are trying to get a match between the 50 ohms side and something around 2000-3000 ohms (I'll use 2500) which is at the bottom end of the (vertical) 1/2 wave antenna. Now, on this design, we have the "liberty" of connecting the 50 ohm line anywhere we want on the matching section.
And, second, if you view the resulting impedance along the line as varying from zero at the bottom (shorted end) to 2500 at the top (antenna feed point), there certainly will be some location (nearer the short) which is at or close to 50 ohms.
The higher the Z0 of the matching section, the higher up you'll have to go to get the best match. I'm pretty sure in is my 1947 handbook (non ARRL) that has one, but it is wires and a wood frame.

There will be, however, discussion regarding the balanced connection on the matching section and the unbalanced coax, but I won't go into there. I'm sure others will...as well as the fact that it doesn't matter which side the coax center conductor should be connected to (doesn't matter).

You can also do a search on "Arrow Antenna" and see an interesting (and oft argued) variation that does not use a short at the bottom.

Digressing even further...telemarketers...

One evening when Wife was out doing schooling, a telemarkerter called. I knew by the blank beginning while the computer connected the next operator.

Tele: "Is Mrs N. Home?"

Me: (somewhat grufly) "She's not here."

Tele: "Is Mr. N home?"

Me: (More Grufly) "Haven't seen him in three weeks!"

Tele: "Oh, then I'll call back at a more convenient time."

C R A C K E D me up.

How do I think of this stuff??

So far, 3/4 times I got the septic additive salesman to hang up on me... "Now, After dumping $175 of your powder down the pot, how will I know if the stuff is really working like you say...." The 4th time, I couldn't shake him...even though I finally told him I was only going on to keep him on as long as I could to keep him from bothering as many others. I had to hang up...shucks!

Don't get the R/S coax. If you can handle the aluminum wire shielding of the cable TV RG-6 coax , use that. Less loss and the 70 ohm vrs the 50 ohm is nothing to worry about. I usually use the RG-8X coax for frequencies below 30 mhz instead of the rg-58. Not that more expensive.

Yet another strange question from yours truly: on the roof of my house, anchored to the chimney, is a large outdoor antenna. No idea which antenna - it was installed before my time, probably 15 years ago (or more) and, for various reasons, I can't climb on the roof to find out. From that antenna and into the house runs a brown cable (or is it wire?) labeled "Belden Celluline 9275 300 ohm UHF transmission" and a bunch of patent numbers.

For some strange reason (it may have been done by the cable company when cable was first installed in the house - also before my time), that Belden cable was cleanly cut mid-way through its run across the basement. While it doesn't look like any twin-lead cable I've seen before (and, admittedly, I haven't seen that many), it has a white core which looks like frozen foam and what appear to be two very thin metal lines, one on each side of the core.

And the question: I want to find out if that antenna+cable setup still delivers a signal. I would like to do it by connecting the Belden cable to a standard RG6 coax and then to a regular or HD tuner. I understand that this connection would require a gizmo called a balun but that's as far as my understanding goes. So what type of balun is it (if there is more than one)? How difficult is it to find? I imagine I need to strip the Belden cable on one hand and the RG6 on the other in order to connect them to the balun. Is it possible and, if so, how is it done?

Thanks.

Typically a 300 to 75 ohm balun will have a pair of screw terminals for the twin lead connection and an F connector for the coax connection. Thus the twin lead simply needs stripping and screwing (yes, I know how it sounds) but the other side will require that you install the appropriate connector on the coax to match to the connector on the balun. Sadly the most common sort of balun to be found has a male F connector and the most common F connector for coax is also a male so you will probably have to come up with a female-female F adapter to match them up.

You can pick up a 300 ohm to 75 ohm matching transformer from Radio
Shack, Wal-Mart or even Walgreens for a couple of bucks. The 2 wires
from your existing flat cable connect to one side and a coax cable
connects to the other through a standard F connector.

Years ago (Before Caller ID) I had the same heating and air
conditioning company call me over 30 times in one week. Nothing worked
with this woman. She was insistent that I just HAD to have my central
air conditioning "Tuned up", even after I told her repeatedly I didn't
have central air, or even a window air conditioner. Finally, I asked
her how many incoming phone lines they had, then I told them that if I
got one more call from them that I would contact everyone I knew to have
them call and pretend to be interested in their repair services or to
buy a new system, then give them fake addresses, or just keep the phone
lines tied up to prevent real customers from being able to reach them.
I was informed by her that it was harassment, but I just laughed and
asked how they would know which calls were real, from the others. I
asked why I should return the harassment I had received from her all

week long. She never called me again.

That old twin-lead cable reminds me of the setup in our city apartment
building back in 1961. The twin-lead was connected directly to the
back of the TV with screw terminals. Occasionally a wire would break
and it would be necessary to re-attach it. The problem was how to
strip it... The plastic dielectric was the most awful, stiff material
around.

Thankfully my father showed me the way. He lit it with a match and
burned away the plastic from the bare copper wires. I still remember
the drip drip of hot plastic and the nasty smell it produced.

There weren't many stations, just the ABC, CBS, NBC and a struggling
PBS affiliate that ran shows about "math lessons" for educational TV.
There was also one big-city independent station that ran Laurel &
Hardy, Abbott & Costello, the 3 stooges and some fine local children's
programs.

Every few months a tube on the set would go bad. Then we called the
Zenith Repairman who brought no less than 3 giant tube caddies and
filled up the living room with spare replacement tubes when the cases
were open. Later, every drugstore had a tube-tester available and we
could test and sometimes even replace our own tubes.

There you go, 300 ohms. Just like other flat lead.

This white foam might be easier to strip than the flat plastic.

You could use screws and nuts to attach this current antenna to the
flat lead side of impedance matching transformer, the small white or
black cylinder 1 3/4inches by a half inch, with flat lead coming out
of one end, and the coax connector at the other end. (Between a
dollar and 2.25. Though only surplus and hamfests charge a dollar.)

And later you could solder the leads if you wanted to.

The female coax connector on transformer will fit well with the male
one on the piece of coax cable you will buy or make.

Some bigger wider ones have screw terminals for the flatlead, and if
the washer has teeth, supposedly you don't even have to strip the
wire. And they may have coax wire coming out with a male connector.

That's when you'll need a M-M adapter, only about 2 or 3 dollars They
sell bothl M-M and F-F adaptors.

www.mouser.com has everything.

I haven't done it, but I think you can just connect the flat lead to
the coax input of a tv, and you'll still get a picture, even if it is
not the best quality. Stick one wire in the hole and touch the other
lead to the threads. Still, I guess if there were no picture, I'd
still try it with the matching transformer.

I used an outdoor antenna in Indianapolis in the 60's and NYC in the
70's and 80's, with flatlead. I didnt' do anything about lightening
protection in either place, and never had a problem. But maybe I
wouldn't do these hookups during a lightening storm. Don't know
whether that caution is necessary or not.

In Brooklyn, I was up on the roof of the apartment building and found
an antenna above my apartment. No one else seemed to be connected to
it, and the wire ran right by my window, so I just connected myself
for 10 years of ghost free viewing.

> My "Electronics Equations Handbook" gives the specifications
> for a "SINCLE-WIRE ABOVE-GROUND TRANSMISSION LINE" including
> Z0, C, L, and resistivity adjusted for frequency.
==========
Single-wire lines -

Primary Constants :
The single conductor has resistance and inductance.
Resistance includes radiation resistance.
Space and its contents has permittivity, permeability and conductance.
The 'return path' is space and whatever it contains.

Secondary Constants :
Phase shift and propagation velocity.
Attenuation (loss).

All parameters obey the classical mathematical rules of Maxwell and
Heaviside.

There are also, very common, 2 and 3-wire (3-phase) transmission lines
which have smaller radiation resistances, but radiation resistances
they DO have depending on conductor spacing.

Reg.

Thanks, the impedance of the half wave section is what I really
needed.I was figuring 5 to 10K. The info you and Cecil gave me got me
back on track
Installing a ground system here is very impractical. I wanted to see
how well the J antenna worked. If performance is acceptable I plan to
further experiment with multiple frequenciey antennas, an HF version of
the Copper Catcus. For now I would be happy just to get this antenna
working on one frequency.

> "antenna

The thing with random wires is that you get a voltage loop at the end and
then voltage loops every half wave back towards the feed end. At the
feed end you will have some random combination of reactance and
resistance to feed, which will tend to require a tuner. And you'll want
a counterpoise to ground it all. For that a quarter wave of wire will do
(or a half-wave attached to the tuner's ground post in the center).
Without a good counterpoise, your tuner and rig may get a bit hot RF-
wise.

Thanks. Your installation is almost identical to mine:
-- FT-857, 100 watts on HF, 25 or so on VHF/UHF
-- Antennas mounted on the rear corners of the bed, in the rear stake holes.

I'm using double-braid RG-8X.

One of the ARRL Antenna Compendiums describes a 4-wire transmission
line whose Z0 is selectable depending on how the wires are connected.

Thanks everyone for the info. One piece is still missing (at least for me) - how do you actually strip a clean cut twin-lead wire? Beachcomber's retelling of his father's method - burn everything around the wires - sounds good, except that if I do that in the basement (where the wire terminates and air circulation is minimal) - the resulting smell will probably be grounds for divorce and a major violation of zoning regulations :)

Nevertheless, I'm willing to use that method as a last resort. Question - is it actually the last resort?

Thanks. I have two coupler systems, one with very good directivity and one with only moderate directivity. The antenna is resonant at about 141.6 MHz. There is a difference of about a couple of hundred kc between the systems.

Now on the the "R" measurements. Both systems indicate an antenna resistance of over 30 Ohms. This antenna has been modeled with three different models. They all indicate a Rr in the range of 5 Ohms. The antenna is grounded by a 3 foot by 5 foot screen mesh. While this is not infinite, it should provide a good ground. Do you have a suggestion of where to look for the discrepancy?

Hi...

Not only smell, but lots of smoke :)

Back in the good old days (around the time sunshine was
invented) I would have done it in your house by putting
the lead flat on top of something hard and not important...
the top of my caddy, perhaps). Then with a knife I'd cut
a slit clean through it alongside each of the wires for an
inch or so. Next fold back the resulting center piece and
cut it off. Now you're left with what for all practical
purposes is just two separate wires, easily strippable with
side cutters or your knife.

I hope that's well enough explained. :)

Take care.

Ken

872. New 4nec2 version

>Well, there's the problem. You stopped your dipole where
>your vertical started so any comparisons are bogus.

Bogus? How so?

>Your
>dipole was an NVIS antenna. :-)

And I want it to be.

It's not a fair comparison
since the vertical was given a 2x height advantage. (That's
like putting my three foot six inch grandson up against
Shaquelle O'Neal in basketball. :-) Put the dipole at 70
feet, like the vertical was, and see what happens.

I mounted both as high as they would go. I don't consider
the GP as having quite twice the height advantage due to
the current distribution.

The top of my vertical was at 53 ft. and my dipole was
one of its upper guy wires at about 50 feet so the two
heights were essentially opposite yours.

No , just different..

Which brings up another question. If the top of a vertical
is at a certain height, what height of dipole would be a fair
comparison?
Dunno...But max current on the GP as at the base..

>It is certainly unfair to compare feedpoints
>at the same height, like you did.

No, it isn't. I can compare any setup I like. I'm not
trying to be fair. I don't want both antennas to act
the same.

It may also be slightly
unfair to compare them at the same maximum heights, like I did.
It seems a fair comparison might be made when half the vertical
is lower than the dipole and half is higher than the dipole,
i.e. the height of the dipole is at the midpoint of the
monopole?

I don't think it matters a whole heck of a lot. I never intended
for my dipole to be a dx antenna. Thats the whole purpose
of putting up the GP. The dipole is for NVIS and medium

range. The GP is for long range.
MK

In a pinch a little tube type adaptor with 300 ohm pig tails could be
directly soldered to the twinlead. Also a combiner with a 300 ohm port
will typically have a male F.

Dan, the frequency difference is most likely caused by the poor directivity of one of your couplers, so would not worry about it. Just take the reading with the better coupler. The forward power coupled into the reverse port will cause a phase error.

As for your modelling: what program are you using, and how do you describe the ground screen? I ran a quick model above a perfect ground -- using NEC2. According to my program the input impedance is 36 ohms at resonance. The radiation efficiency, with a copper conductor, is 99.6%, so the radiation resistance is obviously very close to 36 ohms. I can run a model with a ground screen, but would like to replicate your structure as close as possible. The actual height of my model monopole is 0.505 m (19.88"), and is resonant at 141.8 MHz.

Since you have the foam filled stuff it's a little more difficult to
trim away the center so I'd use a utility knife to make a slit along
each side and pull the wires out. Then just cut away the remaining
center carcass. Finally, attach the leads to the wire leads or screw
terminals of the matching transformer.

Careful about assuming that a 1/4 wave stub will do the trick...

To match a 50 ohm line to a 2500 ohm load using a shorted stub at the
transmission line end and a section between the 50 ohm line and the
2500 ohm load requires (using sections shorter than 1/4 wave for each):

50 ohm stub & section: 8.2 degrees & 81.9 degrees
75 ohm: 8.3 & 82.1 degrees
100 ohm: 8.5 & 82.2 degrees
150 ohm: 9.0 & 82.6 degrees
200 ohm: 9.8 & 83.3 degrees
300 ohm: 15.0 & 85.7 degrees
350 ohm: 45 & 88.9 degrees
353.55 ohm: 90 & 90 degrees

Note that the last on is the case of not using a stub (90 degree stub
looks like an open circuit). The 1/4 wave line impedance should be
sqrt(Zin*Zout).

You can adjust the length to tune out reactance, too.

But if you're matching resistive load to resistive line, the total
length of the stub part and the series part will be longer than 1/4
wave, and more so as the impedance of the stub and series part rise.
You can't use this arrangement if the stub and series section
impedances are higher than sqrt(Zin*Zout). SO--beware of spacing the
two too far apart!

Cheers,
Tom

There's no "fair" comparison between two such different antennas, if your goal is some sort of generalized conclusion about which kind of antenna is "better". The only valid comparison would be a vertical at whatever height you can put it at vs a dipole at whatever height you can put it at. Then, with your particular ground conditions and azimuth and elevation angles of interest, you can decide which is better. Any general binary conclusion about whether a vertical or dipole is "better" is nonsense, so there's no point in making rules for comparing them.

I was in error in saying that a transmission line must have two
conductors. The "G-Line" is the one exception I know of. But it
certainly doesn't function in anywhere near the same manner as a buried
radial. I'm afraid only Reg knows how his "R-Lines" work.

24 db *when* for all that matter. I would note that my vertical *is* indeed about 2 S units noisier than my dipole. And some signals come in stronger, and some come in weaker. My guess is that it depends on where the signals originated from, smarter people may know the real reason.

The J-Pole and End-Fed Zepp design program in George VE3ERP Murphy's freeware HAMCALC package of over 300 radio programs yields results consistent with this litte known fact about the so-called "1/4 wave" matching section for J-Poles. The program is a version of Gary N3GO O'Neill's program from his Communications Quarterly article on the subject.

The latest version 80 of HAMCALC is available at CQ magazine's web site.

<http://www.cq-amateur-radio.com>

By the way, the matching section for the proposed vertical antenna doesn't have to vertical, does it? Can't it be run horizontally and the overall height reduced from about 50 ft to about 33 ft? As mentioned a L network with an inductor and capacitor would also work instead.

I give up!! Obviously my 52 years of mobile installations were all wrong!

A vertical fed against ground is by definition a perfect match for coax.
There is no need to make it a 'balanced system'. If rf exists on the
coax there is a poor ground in the system that should be addressed and
solved.

It really pisses me off that you cant find tube testers in drug stores
any longer. Whatever happened to "SERVICE". I finally had to buy my
own tube tester and now I have to test them alone in my own home. The
drugstore tube tester used to be a great place to pick up women,
particularly those who had broken tvs. It's no wonder there is so
much violence in today's society. People no longer have a place to

gather and test tubes. It was always a big thrill to watch them light up, and slowly watch that meter climb into the "GOOD" (green) zone. That was so much more exciting than all these boring computer games these kids play these days.

By the way, 300 ohm tv cable will still work if it's still properly attached to the antenna and the antenna is still intact. To splice it, strip it back about an inch on each piece. Twist the two wires and bend them down along side the cable. Wrap with tape. Connect to tv and see what happens. On newer tvs you will need an adaptor. A couple bucks at Radio Shack.

old friend,
As I understand your post, you have lost the use of your 6 meter beam and you would like to try a random wire antenna. And as I understand you say that you have a tuner which is capable of working with a random wire.

I would say go ahead and try it. But you can't leave the extra length of wire still wound on the spool. You'll have to make the sacrifice and go ahead and clip off a 50 ft. length or so.

Random wire antennas are not very common on 6 meters, but there's no reason it can't work.

I'm not sure what that inducer is that you intend to leave on one end.

John

Some matching transformers don't require the 300 ohm wire to be stripped at all. I don't know if they're still available, but basically, the flat cable went between two screws. The screws had a "star washer that was shaped like an inverted bowl. When the screws are tightened, the sharp part of the star washer would pierce the insulation on the cable and provide a connection to the inner wires.

More likely you have had one year of experience 52 times.

Consider an eight foot center loaded whip on 80 meters. The feedpoint impedance of the whip is going to be very small - an ohm or two. Worked against an automobile chassis which, capacity coupled to the earth, will have an impedance of somewhere between 10-36 ohms, you will have major imbalance. No amount of "grounding" will improve the imbalance. In fact, just the opposite. The closer you come to the theoretical perfect 36 ohm ground, the worse the imbalance gets.

Now whether this is a problem in a particular installation is a different question, but the imbalance is there. The coax will have a large differential current flowing on the outside as a direct result of that imbalance. Some authors will tell you how important it is to ground the chassis of your transceiver to get rid of this current. Do that if you want, but I think it's better to keep that current away from your transceiver in the first place. A current-type choke at the whip's base will prevent that current from flowing and will keep it in the antenna and in the car's body where it belongs instead of on the outside of the coax. Done properly, your transceiver's chassis should have no RF on it to need grounding in the first place.

Frank,

The antenna I am trying to model is a center 'loaded vertical'. It is a 4 inch base, 5 turns at 40 percent spacing on a .8 diameter inch form and a 4 inch tip. The material is Num 10 solid copper. I adjust the frequency by stretching or compressing the coil. Currently it is resonant at about 141.7 Mhz. The 8405a shows a phase shift of 1 degree per 30 kc change in frequency.

I have used both the vertload model and the EZNEC model. Both predict an antenna R of about 5 Ohms. The 25 Ohm load shows a 12 db power difference between forward and reverse. The antenna shows a 10 db power difference between forward and reverse.

Thanks - Dan

the indcutor I was reffering wawould have been the spool of wire a or
or quater miles of wound wire surely would have a respectable
inductance

I would have rathe rleft it since the anttenna is most becuase I don't
try climbing over some raly icy surfaces is all

tahnk so advice

I don't understand this at all. What does antenna feedpoint impedance
have to do with imbalance?

I know of two causes of current on the outside of a coax cable,
conduction and mutual coupling, and I think I understand the mechanisms
quite well. But neither has anything to do with the antenna feedpoint
impedance. Can you explain what the mechanism is for an impedance
mismatch to cause a current on the outside of the coax?

Roy Lewallen, W7EL

Bill, could you explain what you mean here? Where is the
second equal-magnitude/opposite-phase current flowing?
Through the vehicle chassis? Through the ground under
the chassis? Since the vehicle's counterpoise currents
are necessary for resonance, what good does it do to
choke the coax currents when the coax braid is connected
to the vehicle chassis at both ends?

Doesn't the term "radiation resistance" normally apply to a characteristic
of antennas -- not transmission lines?

901. Antenna Counterpoise

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-25 15:01:45 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <dr83so$4vo$1@nwrdmz02.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 64962

I would like to know the input resistance, at resonance, of a
1/4-wavelength counterpoise, at a low height above a ground of known
conductivity.

It will require modelling on an NEC-type program which takes soil
conductivity and very low heights accurately into account. If there
is such a program!.

The counterpoise can be modelled as a low-height, Inverted-L antenna
with the vertical and horizontal sections totalling 1/4-wavelength.

Modelled at approximately -

2 MHz and 10 MHz.

With heights above ground approximately -

0.005, 0.1, 1.0 metres.

With wire diameter = 1.6 mm or 14 awg.

With ground resistivities -

50, 200, 1000 ohm-metres.
(20, 5, 1 milli-Siemens).

I am interested only in input resistance. Input reactance will be
small when near resonance. Input resistance will not change very much
in the vicinity of resonance. So obtaining exact resonance is not
necessary. I would be happy with resistance values accurate to within
15 or 20 percent.

If anyone has a suitable modelling program and the time to spare I
would be very grateful. Just one or two figures would be useful.

Reg, G4FGQ.

~~~~~~

The impedance mismatch I was talking about is between the halves of the antenna, not between the antenna and the coax. A mobile antenna with a typical center loaded whip operating on a relatively low frequency such as 80 or 40 meters is severely unbalanced in that respect. That does not mean it won't work or is inefficient or anything of the like. Only that it is unbalanced, much like a non-resonant long wire worked against ground.

The coax braid may be connected to the chassis at the antenna end, but not at the transceiver end, and the result is often a "hot" chassis. Some "experts" advise to ground the chassis with a short, heavy conductor to cure the problem, but I feel it's better to keep such currents off the coax to begin with.

That does not mean such methods don't work or are inefficient. I have operated both ways and both ways work. I just prefer not trying to "ground" current which should not be there in the first place.

It's not every day I post a followup to my own message, but it seems appropriate here.

If you would like to experiment with this, try operating 17 meter mobile. If your installation is like mine, the length of coax will be very close to 1/4 wave on 17 (about 13 feet) and the transceiver's chassis will be "hot" for RF. We all know about a 1/4 wave conductor grounded at one and what happens at the other end.

I believe - correct me if I'm wrong - that current on the outside of coax is not subject to the velocity factor issue because what's inside the coax is not involved. It's just like a piece of wire in this respect.

It would be interesting to try it with a 26 foot coax but I haven't gotten around to it yet. Most likely it would only be effective on the one band anyway, since 17 isn't harmonically related to any other HF band.

I'm certain everyone is breathlessly awaiting a status report on this project, so here goes: As suggested, I bought an Xacto knife from the nearest Radio Shack; I rummaged and found somewhere a balun transformer. [As an aside, on the balun are inscribed the magic words "Sega Genesis"! If memory serves, that video game system was prevalent at the time dinosaurs still roamed the earth, although dinosaur and video game historians may quibble with the dating.]

I used the knife to strip about ½ inch of the twin lead wire and embarked on the mother of all kludges: I sort of connected the exposed twin lead wires to the input of the balun; connected an RG6 coax male-F to the female-F on the balun; connected the other male-F end of the cable to the coax input on a Radio Shack Accurian Over-the-Air HDTV ATSC tuner (now discontinued, but the best $90 I've ever spent); connected an S-video cable to the S-video out on the tuner and connected the other end to the S-video in on a Philips RF modulator (best $8 ever spent); connected yet another RG6 to the coax out on the RF modulator and the other end to the coax input on an old (about 15-20 year) RCA TV in the basement.

THEN! I turned on the ATSC tuner and the RF modulator and the TV, and set the TV on channel 3 - and every OTA HDTV station known to man (at least in my area - western Nassau County, Long Island), was there - loud and clear! (Well, not so loud - sharp-eyed readers may have noticed I didn't bother with the audio settings; this was just a test of the antenna and wire).

So thanks be given to the gods of unknown antenna manufacturers and to Belden - a 15-20 year old system is still working, with the flimsiest of setup and no amplifiers! The wonders of technology.

A physical 1/4 wavelength (234/f) counterpoise is not
resonant at low heights so you must be talking about
an electrical 1/4 wavelength? For a fixed length, the
resonant frequency will change with height.

Can EZNEC be used for some of the configurations?
For instance, given my ground description (0.005, 13)
set for EZNEC, a 62 foot dipole one foot above ground
has a feedpoint impedance of 97 ohms on 7.188 MHz. Would
that imply a radial impedance of 48.5 ohms? The same
dipole 0.1 foot above ground shows an impedance of
112 at 5.94 MHz.

It seems as the wire gets closer to ground, the feedpoint
virtual impedance increases because the forward and
reflected waves on the radial are attenuated by the
ground. This rise in impedance is sometimes separated
out as "ground-loss resistance".

Roy, can NEC4 be used to model an underground dipole?

Yet another troll. This is another facile introduction to how you
would do it yourself to prove all the nodding heads wrong.

Then you will rummage up an unzipped program and offer it as the last
word.

Then you will sneer at software users as troglodytes who cannot rub
two brain cells together to derive Lord Plushbottom's principles of
transmission loss off a cable being draped across the bottom of the
Atlantic.

Of course, I will leave you with the last 27 or 13 posts in rebuttal
as this will play out to its obvious conclusion.

Thanks Tom this is the kind of info I need. Hacked a test antenna
together this morning usin chain fence top rail. Spacing i 8 inches for
the stub.Planed on tuning the length of the stub by adjusting a
shorting bar at the bottom so antenna was intentionaly made a little
long. Final length of the 3/4 wl part is adjusable too. Since it is
mounted to the house I figure with the help of friends we can lower
it, tweak it and have it back up again in 15 minutes or less. Probably
be the weekend before I can do more to it.

Source record: 64973

My antenna is a Butternut HF6V vertical. This antenna is ground mounted and has 32 radials, which have been laid on top of the grass. The average length of the radials is about 30 feet. I operate primarily on 40 meters, and I seem to receive good signal reports.

Today, I ran into another operator on 40 meters, who told me that I would get a large signal improvement if I increased the number of radials from the current 32 to 100 or 120. In fact he said he had seen information on the SteppIR website (http://www.steppir.com/) that supported his assertion. Remembering how hard I had worked to install my existing 32 radials, I responded that the effect of quadrupling my radial count would probably give only a small increase in gain of less than one dB. Indeed Cebik's website (http://www.cebik.com/gp/gr.html) seems to support this view with a graphic titled "Radial Length vs. Number of Radials". If I am interpreting this graphic correctly, the gain increase from 32 radials to 128 radials is about 0.5 dB.

Any comments would be gratefully received.

Hi John,

Well, if you read the site closely, there are far more variables
involved than one graph offers a final answer to.

On the other hand, if this graph accurately represents all those
variables converging on your conditions; then, yes, it is a huge
increase as reported. You can, on your next QSO offer to that
operator that it probably will boost your signal one half of an
S-meter needle's width.

> Thanks - Dan

Dan, I have modelled a 5 turn inductor, 0.8" diameter, varying in length from 0.8" to 1.6". The inductance values are 380 - 490 nH. An, approximately 9" long monopole, with a 5 turn helix appears to be resonant at about 190 MHz, with a highly reactive 6 ohm input impedance at 141 MHz. Using a lumped element simulation the required load inductance, for 141 MHz, is about 600 nH.

The only way to resolve these discrepancies is to do a standard single port network analyzer calibration and measure the actual input impedance of the antenna.

Frank

All,

Has anyone tried this successfully? If so what OS and level did you use? I tried, the installation went issue however attempts to execute the app result in an error: 50003.

Has anyone successfully gotten this to work?

Thanks - Dan

Many laptops now-a-days have mini-pci wifi internal wifi cards for wireless internet. Laptops such as the IBM Thinkpad series apparently have an antenna built into the top of the display, which enhances wifi signal.

Does anyone have any idea what type of antenna is used? A neighbor has a wifi coverage problem and he says he measures a (DC) short circuit at the little coax coming from this built in antenna. I suspect this might be normal, but would like further opinion here. Thanks.

I believe that some of them use an inverted-F configuration or
straight-F configuration, either printed right on the PC board or
mounted above it. My recollection (and brief Googling on the net)
suggest that such antennas use a shorted inductive stub as part of
their matching/tuning arrangement, and will thus look like a short
circuit at DC.

Frank,

I will re-measure the coil dimensions. The recall the coil measured 600nH. That is the value I used when I modeled this antenna using EZNec. It showed resonance at about 145 MHz and 12 Ohms. (That was using an average real ground.)

If I assume the antenna measurements are correct then is it the ground that accounts for the difference between 6 Ohms and the modeled 12 Ohms?

Now I am on to model and measure a center loaded dipole.

Dan

923. Questions about Plane reflector

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-26 04:19:04 UTC
From: David <dhuisman@bigpond.net.au>
Message-ID: <Y4YBf.227213$V7.97684@news-server.bigpond.net.au>
Source record: 64884

I am "playing" with a plane reflector at 920 MHz.

The physical construction is a copper sheet as reflector (290mm x 240mm).

A single dipole is mounted in the centre vertically.
The dipole consists of 2 aluminium rods that are 6mm diameter and
the length between the tips is 123mm.

I seem to get a double dip of lowest SWR at 908MHz and again at 945 MHz
(I am not sure of exact SWR but it is closer to 1:1 than 2:1 - I set up
a SWR brodge and noted 1:1 level and 2:1 level using calibrated loads).

The design was scaled from Cebik's 432 MHz version. The calculated
length of the dipole should have been 134.8mm.

My questions are...
1. Why do I see a double dip in SWR instead of single dip
2. Why is the element length so short compared to calculated lenth (I
want antenna to operate at 920MHz)
3. Should I have a choke (Say 5 turns of the coax on a 10mm diamtere at
the feedpoint ?

Thanks in advance for any help.

(Just in case you are curious, I wanting to use the finished unit as a
reference antenna to compare antenna gains)

Dan,

Be interested to see what the exact dimensions of the coil are. Anyway, it seems we have some agreement on the 600 nH value, although my physical NEC helix models do not agree based on my estimate of your coil dimensions. I understand that EZNec uses a "Minninec" ground, which allows antenna contact with a perfect ground, but uses actual ground parameters to analyze the reflections. I am not sure about this, but would assume from the point of view of the input impedance, that the ground would be considered perfect; and therefore lossless. I also noticed I had some borderline NEC warnings when attempting to construct a coil with #10 AWG, so sometimes had to resort to a much thinner conductor.

My models showed about 17 ohms at resonance when connected to a perfect ground. The only time I observed impedances as low as 6 ohms was far from resonance when the antenna was highly capacitive. Ideally I should construct a ground screen, but for the time being will consider a perfect ground.

A free space dipole might be easier to model, but I am curious to understand why there are discrepancies in the monopole modeling.

Frank

PS, be interested in any comments on my NEC code:

> against ground.

Guess I don't understand what you mean by an impedance mismatch between halves of an antenna. Can you elaborate a bit, and how it causes current to get to the outside of the coax?

There's no reason a non-resonant long wire worked against ground should produce more current on the outside of a coax feedline than a resonant one. The conducted current on the outside of the coax is determined by the relative impedances to ground of the two available paths at the shield connection at the end of the coax. In the case of a grounded antenna, the ground system is one of the paths. The other is the outside of the coax. If the ground system is any good, its impedance is much lower than the outside of the coax, so very little current flows on the coax. Changing the "antenna" makes very little difference to the relationship between those paths, so it has very little effect on the current conducted to the outside of the feedline. You can find a more detailed explanation at http://eznec.com/Amateur/Articles/Baluns.pdf.

> "ground" current which should not be there in the first place.

Unless you're using the shield strictly for electric field shielding at very low (like audio) frequencies, you should *always* connect the shield at both ends, with low inductance connections. Think of a rig with an SO-239 connector. There's current coming out of the center pin, and there's an equal amount flowing in the opposite direction on the inside of the shell part of the connector. And inside a coax, there are equal and opposite currents on the outside of the center conductor and the inside of the shield. If you connect a coax to the rig via a properly installed PL-259, all the current on the inside of the SO-239 shell ends up inside the coax shield, and all the current from the SO-239 center pin ends up on the coax center conductor. Both sets of conditions are satisfied, and there's no current left over to flow on the outside of the coax or the outside of the rig. But what happens if you cut the shield at the rig? Then the current on the inside of the SO-239 shell has nowhere to go but over the edge and over the outside of the rig. And the current on the inside of the coax shield flows over the edge of the coax and along its outside. Somehow there'll be a path between the two, by conduction or coupling -- otherwise the rig would see an infinite impedance and no current would flow at all. But you probably won't like the path the current takes. It'll cause radiation from whatever it flows on, and because of the path impedance, RF voltage drops will be created between the coax shield and the rig, and anything else in the path. You might be able to alter its path with "ground"

wires and such, but you'll have a lot of trouble controlling it, and it'll always be flowing somewhere besides where it should be -- on the inside of the coax.

If you have your heart set on using one of these amps, like for instance a
0.3db noise figure, get a DC block for the TV side. Other than that, it
sounds like it may be junk, and you would be better off with a
ChannelMaster.

p.s. To get help editing the Nec2 or Nec4 cards, select the 'Nec editor'on the settings menu or avoid all Nec related stuff and use the drag and draw style editor.

Arie, what I like about NEC are the NEC cards. I have been using NEC for so many years I feel lost without direct access to the deck. Anyway your comments are appreciated, and I guess I should read the help instructions.

You mention "Nec 4 cards". Do you actually support NEC 4? I plan to obtain a license for NEC 4 in the near future, and your interface looks interesting; The cost of GNEC from Nittany Scientific is a bit high, but thought it is probably the only way to run NEC 4 on a PC.

Frank

In the US the ARRL has a lot of good books on antennas -- look on their web page (http://www.arrl.org) for information.

I gather from your English that you are from out of country. I don't know what will be available for you locally. You can probably get the ARRL books. If you cannot get them easily your country or another that shares the language may have a strong amateur radio organization with good books that you can get your hands on.

Thanks to all who replied -- I certainly appreciate everyone taking time to help me. Of course, as usually happens with newsgroups, the thread wandered somewhat from the original question -- which was how to route my coax and mount my rig so as to avoid firing the seat belt retractor.

I have solved the problem -- the dealer had a tech bulletin that told me to keep coax 12 inches from the retractor and to ground everything -- so -- I drilled a 1-inch diameter hole in the floor board under the driver's seat and installed a plastic plug in the hole. I drilled two 1/4-inch diameter holes in the plug through which I routed the coax -- one cable for HF, one for VHF/UHF. Grounded the negative power lead to the chassis in the engine compartment; grounded the rig (which is under the driver's seat) to the frame by loosening a seat mounting bolt and grounding one end of a pigtail to that bolt and the other end of the pigtail goes to the rig's chassis.

The stake hole mounts have mounting bolts in their bottoms. Remove the tail light assembly; drill a 5/8-inch hole in the bottom of the bracket in the stake hole; grind off the paint from around the hole with a Dremel tool; put star lock washers on the bolt that comes out the bottom of the stake hole mount and tighten the living shit out of the mounting bolt, thereby grounding the antenna mount to the chassis sheet metal. There are already factory-installed ground jumpers connecting the sheet metal to the frame.

Fired it up at full power and nothing bad happened; SWR looks good; ATAS-tunes normally; made a few contacts on HF, VHF, and UHF.

I'll post photos, etc., to my web site in a few days when I get it all cleaned up.

You'd be somewhat better off running the power-ground wire all the way
back to the battery, and connecting directly to the battery's negative
post. Include a fuse in this line just before it connects to the
battery negative.

Avoid using the body frame for high-current power supply ground
return. It's too easy for noise from other portions of the
electronics to get into your power, due to the non-zero resistance of
the shared ground path.

Clamping a couple of RF-suppression ferrites onto each coax at various
points along their runs might also help block, or dissipate, any RF
which does try to come back along the coax.

>The stake hole mounts have mounting bolts in their bottoms. Remove the tail

>grounding the antenna mount to the chassis sheet metal.

Adding a corrosion-preventive antioxidant paste or cream between the
chassis, washer, and bolt is a good idea, also. It'll help make sure
that infiltration of oxygen and moisture does not cause this critical
grounding junction to go high-Z in the future.

There are numerous such pastes/products on the market. The one I used
is a copper-loaded grease marketed by Butternut, under the cutesie
name "Butter-it's-not". You might be able to find an equally usable
copper-grease at a good auto-supply store.

Source record: 64905

Hello!

I just bought this: http://www.rustindustries.co.uk/remote.htm
The range is only 10-15 meters in free air, only 5-7 meters indoor.
Is it possible to connect a whip type antenna?
I have calculated a length ca 17 cm.
But i cannot see where to connect the antenna.
The transmitter has a loop style antenna, powered by one transistor and a
oscillator of some sort, i have drawn a schematic:
http://media.openbloc.com/1tpwr
I have tried to connect the antenna to the collector, but that gave me no
output at all.

Regards

Carsten Hjorth

I looked at the design of a similar 433 MHz nonlicensed transmitter a
couple of months ago (it was for an IR-remote-to-RF repeater system).

It looked to me as if it was using the loop both as part of a tuned LC
tank circuit, and as the radiating element. I suspect that the same
is true of the circuit in your transmitter.

Adding a length of wire to it would very probably de-tune the tank
circuit. At best, it'd oscillate and transmit on the wrong frequency.
At worst, the wire loading would de-Q the tank to the point that it
wouldn't oscillate at all.

To boost the transmitter power or the antenna gain (if doing so is
even legal under your RF-use rules) would probably require a
significant redesign of the circuit.

In your situation, would it be adequate to boost the _receiver_ gain
instead? You can probably do anything you want, legally, to the
receiver... add a collinear antenna, change to a Yagi, use a corner
reflector, etc.

What country are you in ?

The device is made in the UK and European EIRP limit should be 10mW.

We make low power transmitters at 433 and 915MHz and find we normally
get over 20m even with a resistor dummy load across the antenna terminal.

We made a transmitter in a plastic wristwatch that the oscillator
coupled directly into a loop antenna (you need to move the collector
connection along the loop till you get best match). This unit had
radiated power of around 100uW and still achieved 100m range.

Our 10mW units achieve over 1km line of sight outdoor range typically.
I cannot imagine a range of only 5-7m (unless the receiver is extremely
insensitive or the transmitter and receiver are not tuned to the same
frequency).

Social Security is in trouble because when they figured the original
numbers, the average person lived to 65, so the government thought they
would, more or less, never really have to pay anything significant out.
That changed due to decent medical science, as most people in this
group (rraa is where I am right now) are more than aware.

Social Security has been busted for more than a couple decades, and none
of the bastards in the Senate or Congress or the Administration have had
the balls to let it just disappear. It is a dinosaur. And please note
I never mentioned a party here, since all are guilty of just covering
their asses just to get through another term.

And, at 52, I am one of the people that's going to lose evcerything that the government stole from me and gave away in this deal, so don't start ripping me for not caring.

Thanks. I'll do all of that. I can pick up ferrites at Radio Shack and should be able to find the anti-oxidant paste at local auto parts place. In fact, local auto parts has big ferrites -- they sell them as noise suppressors for audio installations.

~~~~~~

I could have worded that better. I meant that the coax is connected to the transceiver chassis but the transceiver's chassis is not connected to the car's chassis directly. I see why some folks took it to mean the coax braid at the transceiver isn't connected to anything.

Sorry for the confusion.

(snip)

Why would that be the best arrangement? No steady state power comes
from the battery. If you want the least voltage drop, you take a pair
of wires back to the alternator, where the power originates. The
only advantage of the battery connection might be lower alternator
rectifier noise in the power, but that is pretty easy to filter out
right at the alternator, before it gets out in the wiring harness and
into the antenna.

HUH???? I've designed enough communication site power
installations to know that the battery powers the equipment and the
function of the alternator in a vehicle or the rectifier (power
supply, in ham language) in a fixed intsallation is to recharge the
battery "on the fly", so to speak. The current capacity of the
battery is much greater than that os the charging device.

Any design that puts the load on the charging device rather than on
the battery would be rejected out of hand. At best. both of them
would be connectable (through switches or circuit breakers) to the
load bus, with separate metering for the battery, the charger, and
the load.

In your scheme the equipment would get no power when the alternator
is not operating, or more clearly, if the equipment DOES get power,
the power must be coming from the battery.

Think about it.

I've never heard of anyone hooking up auxiliary loads right at the
alternator. I can imagine somebody hooking a secondary-battery feed
at this point (in an RV, perhaps) but I don't think I've ever seen
radios hooked up there.

I rather strongly suspect that you'd find the amount of "alternator
whine" in the audio to be significant greater if you hook up the radio
right at the alternator.

Every mobile-ham-radio installation guide I've ever read (including
the owners' manuals) seems to recommend running heavy wires back to
the battery.

Frank,

I will take the coil measurements.

Into which model programs can this description be loaded? Is there a 'howto'. I looked on how to dump my model from EZNec and could not find it.

I have yet to see "any" manual which suggests going to the "Alternator" for
voltage to run a radio, be it Ham, CB, or Two Way or even just electronics
books which may touch the subject of wiring radios or anything else for that
matter - into vehicles. I don't know where this guy read his information,
I'd love to know where the idea came from. My gosh, the whine is bad enough

sometimes at the battery, let alone the Alternator - the mother of it. Most suggestions are to fuse both the positive and negative leads on the radio (going to the battery) - although you can get away often - with grounding the negative and fusing the positive to the battery (for best results) OR to some point to feed the 12 volts if the current supply is ample - ie the cigarette lighter or some other place people tend to use. "I" don't suggest that, but people do use them..... Of course - the latter would be for smaller hand held CBs or the like. Anything larger, you're pretty much left with only the Battery.

I don't recommend fusing only the hot side. Fuse both. It's safer.

Fusing the ground wire protects you against wiring faults. Consider
what would happen if you don't do this, and your radio's chassis is
grounded to the vehicle frame, and if the main grounding strap from
the alternator to the battery comes loose at the battery end. Your
rig's chassis, and its ground wire could end up being a major part of
the ground-return current from the alternator to the battery. The
ground wire may not be able to handle that much current, and might
overheat or catch fire. If it's properly fused, the fuse will blow.

I'm with you - I was just alluding to - in some cases, like CBs, people get
away with fusing only one lead. My personal opinion - fusing both sides is
the only way to go and most manuals I've read "do" suggest "both leads
fused".

I am using a Yaesu FT-857D. The power cord that comes with the radio is approx 8 feet long. At one end is the plug that matches the power jack on the radio. At the other end are TWO inline fuse connectors -- one in the red lead, one in the black lead -- with approx 10 inches of wire coming out of each fuse holder, bare at the end, to connect to the battery (or some other source of power). The inline fuse holders take standard automotive blade fuses. So -- it looks as though Yaesu intends for both positive and negative leads to be fused.

965. Re: 8405a working and measuring resonance?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-27 14:16:42 UTC
From: Frank <ve6cb@nospam.telus.net>
Message-ID: <eXpCf.199081$OU5.8916@clgrps13>
Source record: 64776

Dan, I am running NEC-Win Pro from Nittany Scientific. I do not have any experience with 4nec2, but have taken a quick look at the NEC manual to figure out what the error is.
The "GH" card generates a helix with the base positioned at z = 0. My first "GW" card positions a wire from the top of the helix with a length of 4". Since the GH card position is fixed it must be followed by a coordinate transformation "GM" to position the helix, and the GW 1, card to the desired position. For some reason the last field (ITS field) was filled with a decimal number indicating the range of "Tags" to be moved (000.051 which means all tags from zero to 51, but there are only 2 tags prior to the GM card, so don't know why this happened). In any case this worked on my model. The default entry for the ITS field is zero, or just leave blank. This works fine for me, and just moves the GW 1, and GH card positions as desired.

Experimenting with 4nec2 indicates if the only geometry card is a GH, followed by a GM card, then the transformation appears to work. It is only when there are other geometry cards present that the GM function fails.

More study of the help menu in 4nec2 is required to figure out the correct structure for the ITS field.

Ok Dan, figured where the problem was. It is just necessary to set the ITS field to zero, and the code runs ok.

You might want to do something with the receiving antenna. My 4xx MHz garage
door opener has about 30 meters range.

Hi John,

I once had a 30m Vertical ground mounted with 120 radials and it worked
great.. but it work quite well with the 40 or so I had at first also..
the other dynamic that is at work that you hardly ever hear about is
that as you increase the number of radials say from your 32 to approach
100 or so you also need to increase their length so it approaches
1/2wave for each radial.

as a rule of thumb you should keep adding radials until you see no
further change in antenna input impedance. At that point it is not
worth the effort or expense to add more.

> CORRECTION - I mean to write 90 radials rather than 90 verticals!!!

Heh heh. There does come a point, though, where more verticals will achieve the same result at less expense than more radials. I've found that 8 radials of about the same length as antenna height works well, even with multiband antennas. And a second antenna will recover the gain to the same level as 120 radials (standard broadcast design), plus providing a steerable pattern. Coils eat up as much and can be eliminated, or made smaller with top-loading capacity hats.

Or, for radial-free performance, design it as an end-fed half-wave!

~~~~~~

I think John is right, however I would never do it that way. The extra millivolts you pick up are going to be smothered in alternator noise and if large enough, might actually be too high for the radio. Radios are typically designed to run from 13.8 volts maximum, whereas alternators often put out more than that.

The additional few watts you get from your transmitter will not be noticeable in normal operation anyway.

~~~~~~

If you connect the radio's negative lead (unfused) to the car's chassis you should be ok. A problem can occur if you connect the radio's unfused negative lead directly to the battery terminal, as is often advised.

If the car's ground wire from the battery to the car's chassis ever comes loose and you go to start the car, all the starter current will try to flow through your radio's negative lead and through your coax to where the coax is grounded at the antenna feed point. I have seen pictures of what this several hundred amps does to a radio and it's not pretty.

Most radios today are supplied with a power cord having a fuse in each lead for good reason. Don't defeat their purpose.

You hear about it if you read Devoldere's "Low-Band DXing." [g]

He quotes a rule of thumb developed by a fellow member of my DX club, Eric, N7CL, who says that radial length and number should be such that the tips are not more than 0.015 lambda apart. So if you use 1/4 lambda radials you need 104 of them to be within 0.1 dB of theoretical max gain (over average to good ground). Half this number would reduce the gain by about 1/2 dB.

Of course right above this text in the book is a table that shows for 120 radials the optimum length is 0.5 lambda. So the same book, on the same page has two different "rules."

Personally, my "rule of thumb" is that the radials need be no longer than the physical height of the radiator (<1/4 lambda) and their number follow Eric's rule.

>
>as a rule of thumb you should keep adding radials until you see no
>further change in antenna input impedance. At that point it is not

The problem with this is that the derived number is dependent upon the resolution of the instrumentation. If you can't see a 5 Ohm change, you quit early. If you can resolve 0.1 Ohm, you keep adding wire, even though the efficiency improvement will be insignificant.

A card is a line of NEC code. I guess it is a hold over from the old days
when NEC must have been run with FORTRAN punch-cards on a mainframe
computer.

I�m in Denmark and its frezing...
Should i extend the wip antenna on the receiver? Now it�s a 1/4 wave, should
i try full wave?

/Carsten

Frank,

Thanks for that.

BTW: Does anyone know where I can get the wgnuplot.exe for 4nec2ex ?
The site has a link to the gnuplot only, I tried this link but is brings
up a page error.

Have you contacted the supplier to verify what the typical range should
be and get their recommendation for appropriate antenna ?

Full wave won't work, but 5/8 or 3/4 might work better than 1/4. If it does
not have to be non directional, you could use some kind of an antenna that
has some gain, like a 3 element Yagi. You are in the 70 cm ham band; so, any
of the common 430 - 440 Mhz antennas will work, provided you can connect it
to the receiver.

Frank,

Umm. I tried to set the GM ITS field to 0 and that did not make any difference.
Can you forward the nec file that does not produce the error?

Thanks - Dan

nice boat and nice rig.....
put a 50 ft pine tree on the bow and another on the stern, and string up a
dipole. :-)
or -
- a 5/8-wave vertical for everyday use
and
a 3-element beam for reaching back to shore from way-out.
--- but ---
If you loose the repeater while using the vertical, head back in right
away, because you're too far from shore.

I have been using this antenna for about 4 months now with excellent results. It works very well on all the ham bands up to 6 meters. Unlike the test in the QST article where they mounted the antenna at ground level. The trick is to get it up in the air 30 to 35 feet. In my case, I have the base at about 30 feet in the air. If you can't mount the antenna at the recommended height then look at one of the GAP verticals.

Carsten wrote:
"Is it possible to connect a whip type?"

Probably, or perhaps a dipole.

The wavelength is short. You can get antenna gain without connections if you use reflectors with your existing antennas. The reflecting surfaces can be plane sheets or grids aligned with the polarization of the antenna.

You did not give the size of your loop. If the loop has a perimeter of one wavelength, propagation is broadside to the loop. If it is smaller, propagation is in the plane of the loop.
Polarization depends on where the loop is fed.

Your wavelength is about 0.7 m.

If a perfect flat sheet is 1/4-wavelength behind your antenna, you may get about 5 dB gain in the forward direction from the reflector.

Replace the flat sheet with a 90-degree corner reflector, and the gain rises to 10 dB with 1/4-wave spacing between the antenna and the corner.

11 or 12 dB gain may be obtained by using a 60-degree corner.

For a 1/2-wave dipole spaced either 1/4-wave or 1/2-wave from a 90-degree corner, the gain is about the same (10 dB).

1/4-wave spacing of a 1/2-wave dipole from a 90-degree corner gives a drivepoint impedance of about 85 ohms.

1/2-wave spacing of a 1/2-wave dipole from a 90-degree corner gives a drivepoint impedance of about 125 ohms.

As the 1/2-wave dipole without a reflector has a drivepoint impedance of 73 ohms, impedance upset from coupling to the reflector is significant but not excessive.

See Kraus "Antennas" under the topic: "Corner reflector" for details.

Best regards, Richard Harrison, KB5WZI

Dan, here is the code I copied and pasted it directly from 4nec2 nec edit page. I have not yet figured out how to have swept frequency data, as the program only seems to recognize the first frequency of 135 MHz.

Dave, sorry I am not very familiar with 4nec, so have no idea what wgnuplot.exe is. Most of my NEC experience is with NEC-Win Pro, which is so straightforward and easy to use. Not that I mean to degrade 4nec2, I think the guys have done a great job for the free software. I guess your best approach is to keep bugging Arie as I am sure he knows.

I didn't find it too hard, I followed the links from Arie's page.

Try ftp://ftp.gnuplot.info/pub/gnuplot/ and see if you can identify
the correct binary for your (unstated) needs (presumably one of the
windows versions, probably win32 since you wanted w*.exe).

Frank,

I have now been able to get this to work. Thank you. Open the main window, and then the calculate button, and then select the first option. This causes my system to perform a sweep. It shows a resonance sweep for this model.

I am currently stuck performing a successful update of the input file. I would like to use the windows feature to change the coil spec for instance.

Dan

993. Homemade coils for using an MFJ analyzer as a dip meter?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-28 19:51:15 UTC
From: gsm@mendelson.com
Message-ID: <slrndtnib5.v7g.gsm@cable.mendelson.com>
Source record: 64803

I have an MFJ modle 249 (the original with a meter) antenna analyzer. MFJ
sells a kit of two coils to make it into a dip meter.

I would like to use it to measure the resonant fequency of a traps I
am building, but am unable to purchase the coils.

Is there a way to make then on your own?

TIA,

Geoff.

Ok Dan, glad you have gotten in working. Will try and get my program to sweep. As for the coil you can enter a helix by clicking on "Run", then "Geometry builder". I have not done anything with this feature, but it looks interesting.

Frank

I think I have a spare set of coils for the MFJ-201 dip meter, missing only
the UHF coil. I don't know if the coils are the same for the 247, but if
you can verify that they are the same, maybe we can make a deal.

Email me if you're interested

Hey,

I am trying to find out the different Node numbers for repeaters worldwide. My local 2m repeater is enabled for gettin other repeaters worldwide as i have heard it beind done many times. Is there a website that has the numbers or would one of ye be kind enough to provide me with the info.

Thanks,
Chris

Node numbers? What are node numbers?

I am simple caveman radio operator, and know nothing of the "node
numbers". The repeater I use is at 145.45, negative offset.

Basically if your local repeater is connected to internet, you can dial a
Node for a repeater on the other side of the world. Like echo link just
without the computer.

> battery "on the fly", so to speak.

Sorry, I thought we were talking about a vehicle electrical system. In a vehicle, the battery serves essentially one purpose, to start the engine. After that, everything runs from the alternator, which also recharges the battery over a period of time.

> The current capacity of the
> battery is much greater than that os the charging device.

Are we talking about a transmitter that draws more current than an alternator can supply? If so, I think it is a poor arrangement. I wouldn't connect a transmitter that exceeded the output capability of the alternator, even if it meant I had to upgrade the alternator t oavoid it. I also wouldn't install a tranceiver in a vehicle without adding an RFI filter to the alternator. If it is too noisy to be connected as the power source, then it is too noisy to have connected to the wiring harness, in such proximity of a receiving antenna.

> Any design that puts the load on the charging device rather than on
> the battery would be rejected out of hand.

Not by me, it wouldn't.

> At best. both of them
> would be connectable (through switches or circuit breakers) to the
> load bus, with separate metering for the battery, the charger, and
> the load.

In the automobiles I have experience with, the alternator connects directly to the power distribution bus with one branch of that bus going to the battery, as the recharge path. The battery also has a heavy connection directly to the starter relay, to start the engine, independent of that distribution system. Connecting a big load, whether headlights or transmitter directly to the battery will lower the battery voltage slightly, so that it does not recharge fully. All loads should branch from the alternator output, where the voltage is regulated, including the battery charging branch.

> In your scheme the equipment would get no power when the alternator
> is not operating, or more clearly, if the equipment DOES get power,
> the power must be coming from the battery.
> Think about it.

I'm thinking about it. You are saying that the transmitter draws more current than an alternator can deliver, with the engine running, but you intend to operate it without the engine running. I hope you pack jumper cables. ;-)

Don't bother. I have one and it's a very poor dip meter. Get a Heathkit
or Eico or Millen instead. You'll be much happier.

>or Eico or Millen instead. You'll be much happier.

The MFJ 269 with the dip-meter coils, is probably the least-sensitive and least-usable dipmeter I've tried to date. It really isn't good for very much at all.

I don't think the coil construction is terribly critical, though, since the coil inductance is not being used as part of the oscillator tuned circuit. The MFJ uses only two coils to cover a wide range of frequencies, rather than the half-dozen or so coils used by real tank-circuit dippers.

You can try simply winding a few turns of hookup wire on a convenient tubular form, hooked up to an RCA or BNC or PL-259 glued to the end of the form, and see if you can get an adequate dipping for your purposes.

The higher-frequency MFJ coil seems to be about 4 or 5 turns of wire - length is about 1/2" and diameter is somewhere around 3/8". The lower-frequency coil is somewhere around 12-14 turns of wire, close-wound on a 1/2"-diameter plastic form.

As dippers go, the Heathkit HD-1250 solid-state model (it's a dual-gate-MOSFET-based gate-dipper rather than a grid-dipper) is better than the MFJ. It's not great, but it's probably adequate for most purposes.

Haven't used a Millen but I've heard that it's better yet. Haven't used an Eico, or one of the B&W model 600 acorn-tube-based grid dippers.

The Measurements/Boonton Megacycle Meter is the ne plus ultra of dippers, as far as I know. It's big and perhaps a trifle clumsy, but it has a strong oscillator which *really* dips nicely with even very loose coupling to the circuit being measured. If you ever run across one, grab it.

For comparison: when testing an air-core inductor in parallel with an air-variable cap, I could barely get a dip reading at all with my MFJ and either of its coils. The coil had to be poked right up into the inductor and into contact with its windings to create enough coupling for a dip... and of course this tends to de-tune the coil and makes the measurement less accurate.

A Heathkit HD-1250 would get a usable dip with its coil as far as an inch away from the inductor.

A Boonton got a dip three or four inches away.

Thanks for the information. The whole purpose is to avoid paying 180 UKP
for a multiband trap antenna. I have access to coax and plastic pipe,
so I was hoping to make the traps myself.

As for buying an Eico or Millen, I doubt that there is one in the entire
country yet alone for sale, :-(

73,

Geoff.

Thanks,

Hopefully it won't have to be very good. I need it to make a trap antenna, I found what I want for 180 UKP (plus shipping and taxes), but simply can't afford it. In fact, buying the $20 coils is a stretch at this time.

I have plenty of coax and plastic pipe is easily available.

It did seem awfuly cheap, the same range in their dip meter was covered by at least five coils.

Ok, thanks, it may be exactly what I need.

This sounds good to me, I should be able to duplicate that.

Heathkit? What's a heathkit? I have not seen one in the nine years I've been here. A friend supposedly has a heathkit HF rig in boxes from when he moved here, 25 years ago, I'm sure he hasn't even turned them on in at least five years.

> The Measurements/Boonton Megacycle Meter is the ne plus ultra of

In a country there are no hamfest, no swap meets, no ham radio stores,
and you need to get permission from the Ministry of Communication to
buy a new rig (pro-forma, but it must be added to your license),
I expect that I'll never run across one, even if I hunt it down. :-(

73,

Geoff.

Thank you, it's exactly what I needed. I am having trouble with one point.

The wire type in the table is CuL and CuAg. Obviously CuL some sort of
copper wire, with the CuAg, being copper and silver (silver plated copper?).

What exactly is CuL wire? Is it critical that I use it what ever it is?
Can I use plastic covered copper wire?

For the high freqency coils I can easily get 2.0mm stiff copper
wire for use in electrical conduit. It comes with some sort of insulation,
probably PVC. Can I use it, and if I do, should I remove the insulation?

Thanks in advance,

Geoff.

~~~~~~

Really? Then you should have an alternator which could supply the
starter motor too, with that thinking.

The battery is there as a power source for intermittent loads. Use it.

Have you ever driven a car with a totally dead battery, after starting
it with jumper cables and running entirely off the alternator? I have
and it's not good. The battery is there for more than just starting the
car. It also stores and smoothes the output from the alternator, much
like a giant filter capacitor. Don't be afraid to use it as such.

Geoff and all:
The 'dip' function is simply a 2- or 3-to-1 series-connected mismatch with a capacitor, resistor, and coil to couple to the device-under-test. The dut makes the meter wiggle by absorbing a bit of power, for a visible indication of 'resonance'. That's all, afaik.

1014. help editing 4nec2 model ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-29 16:45:43 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <T_WdndNuJIahbEHeRVn-tQ@comcast.com>
Source record: 64828

All,

I am experimenting with 4nec2 and these are an elementary questions. I have been able to create a 'new' model, see below, using the geometry editor. Here are few questions:

1. when the model loads it shows 4 MHz instead of 144.

2. ground has been set but does not show in the display

3. I am trying to make the middle segment a coil. How is a coil created? When inserting a helix 4nec2 errors with a divide by zero error? The steps would be helpful.

4. Adding a source does not seem to take. I am not sure how how to add a source? How to determine where it is placed?

These are basic, but any help would be appreciated.

Thanks - Dan

I described the separate wiring that allows large current draw from
the battery, intermittently, for starting.

Of course, you can use the battery in ways the auto manufacturer did
not intend. If you want to run a radio for long periods with the
motor off, you can expect the battery life to be shortened, though.
Auto batteries are not deep cycle designs.

Agreed. But I prefer to design and install my own alternator RFI
filter, rather than depend on the battery for that purpose.

The difference is the IR drop of the branch circuit from the power bus to the battery positive, including the fuse link in the harness.

Loading the battery for long periods when the alternator is running is likely (if the regulation point is at the power bus, not at the positive battery ternminal) to result in an under charged battery.

If the regulation point is the battery positive terminal, then the voltage at the distribution bus point will be pushed up to compensate for the unexpected IR drop in the battery branch, and will shorten the life of headlight and other bulbs. (The charging systen is designed so that the battery is normally recharged at a rather modest rate, not at the full alternator output capability.) This is a reason why the regulation point is usually at the distribution bus, not at the battery terminal.

~~~~~~

Depends on whether the battery is fully charged or not. Immediately after starting the engine, the voltage difference will be at its greatest. After a few minutes running, the difference will be very small, unless a large current drain is occurring.

In other words, there is no single answer.

Hello All,

At Friday 3 februari 2006 will be SUITSAT launched -
from out of the ISS Space Station into space.
In the Space Suit is a a transceiver which send voice
greetings in various languages.
Also SSTV pictures (mode: robot 36) will be send
down to earth.
For those who received the SUISAT signals can
request a special certificate!

Probably you can receive Suit Sat with a simple GP vertical.
Better is an yagi (or trie both to switch).
I hope amateurs will report here how strong they receive
the suitsat signals (and what antenna you have used).

More info you can see on:
http://pd0rkc.ontwikkel.nl

Please publish this message on websites (unique event!).

One comment Dan, you have defined a finite Sommerfeld/Norton ground. In NEC2 the antenna cannot touch the ground unless it is perfect (Unlike EZnec, with its "Minninec" ground). 2.2204e-16 is, from NEC's point of view, zero. At the moment I don't know how to address the other problems, but may play with it later. I have also noticed the problem with the frequencies.

There are instructions provided with the program, but are buried as "Word", and text, documents in the 4Nec2 folder,and in the sub-folder "exe". The NEC user manual is also useful, but will only help with NEC code structure.

The battery is not there to filter RFI - it's there to smooth out
any ripples in the rectified but unfiltered alternator output in the
AF range. AFAIK no automotive alternator has any internal filtering,
and the battery is the best way to provide that filtering as compared
to conventional lumped-constant LC filters.

How am I to know either the branch wiring resistance between the
alternator and the battery in your car, or the current you intend to
draw from the battery while the alternator is running? Some have been
talking about drawing more current than the alternator can supply.

The battery is definitely a part of any alternator filter. But putting a good high frequency capacitor right on the alternator output terminal to the case, and an inductor rated for full alternator output current between the alternator and distribution system (to which the battery is connected) and a second RF bypass at the distribution branching point, back to the alternator case, to block any RF leakage exiting the transceiver supply leads from getting out into the wiring harness, provides a huge reduction of rectifier recovery generated RF (through both the transceiver power leads and from direct radiation from the wiring harness) and 3 phase rectification generated ripple.

That is my run on sentence for today.

The battery is the low frequency part of the output capacitor in this pi filter.

It just seems strange to me to invest all that money in a powerful transceiver and a custom installation and skip these three vital parts.

Frank,

I have made some progress. The trick for adding new source and RLC objects is to select them and then to click, hold, and drag to position. The value option box opens up for setting.

The current model does not sweep frequencies. Have you figured out how to sweep frequencies?

So far these are normal teething problems for a new app. Thanks - Dan

I apologize for giving you that false impression.
This group appears loaded with those, and has no need for another.
I was being a person who had an opinion for some particular and stated
reasons, and was challenging this group to show me my mistakes.

No joy, so far.

What I have gotten is lots of "Thats not the way we do it.", "That's
not the way the experts say to do it." "You are wrong." and "I know
more than you do."

But back to your question, I assumed that you are qualified to measure
the wiring resistance between your alternator and battery and also
calculate (or read the manual for) the supply current of your radio,
and know ohm's law. So you should be able to tell me the difference
in the voltage between your alternator and battery. You might also
estimate what the ampacity of that branch wire (with fusible link) is,
based on the wire gauge of the link. If that current is anything near
your radio's draw, you might worry about operating your radio through
that link, especially right after starting the engine, when the
battery is recharging through it, also. Replacing that piece of wire
is an onerous task in many cars.

"Vital" only if you have a noise problem. I haven't in my last three or four cars. The alternators were perfect gentlemen.

So nice for you!

Well, that is one hypothetical problem with my suggestion that doesn't
apply to those 3 or 4 vehicles. Perhaps car makers have had to reduce
alternator noise (e.g. use soft recovery diode bridges) to serve the
built in receivers and all the other electronics.

Alternator whine is often caused by a bad diode.Replacement(s) may be the most satisfactory fix.

I have never seen it recommended to connect a radio to anywhere but at
the battery terminals. Even if the radio were to be connected to a
junction box designed for this purpose some distance from the battery
you never want the alternator to connect to that same junction. Having
anything connected to the wire carrying alternator current will induce
noise into that power line due to the resistance of the alternator
charging wire.

Most wires coming from the alternator to the battery are rather small,
#10 or #8 wire at best. There is significant voltage drop in that

wire. The noise from the alternator is not just from the average current causing a voltage drop but from the peak current which is much higher.

Every time you turn on the headlights the noise will get worse if the radio is connected directly to the alternator because of additional voltage drop on that line.
If there should be a break in the alternator wire to the battery the surge from the alternator will most likely damage the radio.

The alternator regulator most likely would not be able to handle the rapidly changing load of an SSB radio smoothly causing additional spikes as it tries to regulate.

Need more reasons? :>)

A more common problem I'd be concerned about would be "load dump",
which occurs when a high-amperage load on the car's electrical bus
stops drawing current abruptly - for example, if the headlights are
switched off while the engine's running. It's common for this to
result in a large voltage spike out of the alternator, before the
regulator has time to reduce the alternator output. Spikes of several
dozen volts are common - my recollection is that auto-electronics
manufacturers engineer their devices to be able to stand 50 volts at
their power-supply terminals for a brief moment.

I would expect that the magnitude of this spike would be significantly
greater at the alternator terminals, than it is at the battery, due to
the series resistance and series inductance of the battery-to-
alternator cable, and the battery's low impedance. It's possible that
a load (e.g. radio) which could survive a load-dump spike if wired to
the battery, could be damaged by a higher-amplitude spike from the
same load-dump event which might occur right at the alternator.

It seems clear that the standard, recommended practice is to wire
radios to the battery. It also seems that the original poster is not
satisfied with the justification for this practice (either by
convention, recommendation of authority, or theoretical arguments
posed to far), and that he has some arguments from first principles
which he feels justify a different approach (wiring to the alternator).

In the end, for the original poster to be satisfied (either that
standard practice is the best practice, or that his alternate
suggestion of wiring directly across the alternator is actually
superior) I suspect that he's going to have to fall back on that old
mainstay of scientific discovery - he's going to have to experiment.

He'll have to wire several different radios, of various makes and
models, up to [1] a double-fused heavy-gauge feed from the battery
posts, and [2] an equivalent feed brought back to alternator and its
ground. He can then determine whether his alternate approach actually
delivers more useful current to the radio, whether the transmitter

powers are actually higher, whether there is indeed more alternator whine or RFI on the transmitted signal or the received audio, and whether the radios show any differential in their ability to survive a few months of usage and load-dump spikes without losing their Magic Blue Smoke.

Actual results (either way) trump speculative arguments.

I know of a guy who had an HF radio fry when the voltage to it exceeded 16 VDC - not once, but twice - doing some major damage (a few parts and lots of dollars). He didn't know what caused it the first time to protect it before the second. He thought it was just a fluke (the first time). The point is, anything beyond the rated 13.8 was running a risk - even if accidental. And as argued in previous posts, the whine coming straight from the mother of it - has to be a bear.

I would like to know - where this idea hails from - to begin with, how long "John" has been doing it, how many radios and/or alternators fried from it.

Also, I don't think any or all of us are saying we're all right and you - "John" - are all wrong. It just seems NONE OF US - have ever heard of this being done. WHERE - what book, teacher, etc - got you on the track of doing it this way???? We just all (except you) seem to be in agreement with the way "we" were taught. Maybe you could think of it as say - John Glenn explaining flying a rocket to a cave man. The concept new - unheard of. Not that it hasn't been done - you've said so yourself, ya got to be a good "salesman" to get it across to the masses who've yet to see. You have to know - anything "new" - be it a new drug to fight disease, technique to do surgery quicker and less painless - or Electronics techniques or measurements - will meet resistance until proven.

Maybe - if any of you out there have access to a junk car that runs yet, and you're not afraid to experiment, can grab some junk (but working CBs/2 way radios) - give it a whirl and report back with your own test results. As Dave Platt said in the post above - "Actual results (either way) trump speculative arguments."
I don't have a junk car to try it with..... Maybe I'll go to a junk yard and try to pick one up cheap..... try it a few times. I'd love to see how this works - maybe I can become a believer.

Hello Dan,

to sweep frequencies after having modified or created your model, push F7, select 'use freq-loop', select one of the options 'Gain' (only Gain, F/B and F/R line-chart); 'Ver' (vertical pattern for eacht freq), 'Hor' (horizontal pattern) or 'Full' and specify the start- en stop-frequencies. Then click <Generate>.

B.t.w, did you read the _GettingStarted.txt file ?

Concerning the 144 mhz / helix problem, for now I am not able to reproduce it overhere. I would very much like to know about this, could you give me some more details ?

Arie.

It might well have been the load dump phenomenon Dave described. The cause of load dump is that at any given time, the alternator contains quite a bit of energy. If a good part of the load is abruptly removed from the alternator, the energy is "dumped" into whatever is left connected to it. The result can be several tens of volts or more, with the capability of supplying a lot of current. A common cause of load dump is loose battery terminals, and this might be what happened to the fellow with the blown rigs. The safest thing is to connect the rig directly to the battery posts, not the connectors or connecting wires. Long ago I bought and built a Heathkit SSB mobile rig, and I recall drilling holes in the ends of the battery posts and (gently) driving in some special terminals that came with the mobile supply.

I'll join the chorus in recommending against connecting a rig anywhere but at the battery, and add my recommendation that the connection be made directly to the posts. As several others have said, the battery does much more than start the car. Without it you've got a very nasty supply with the potential to do serious damage.

An additional reason to connect to a point with the lowest Thev. equiv. resistance (battery terminals) has to do with turning off inductive loads. A student of mine told me he once measured just over -100 volts on the line to a windshield wiper motor when the motor was turned off at just the right time. (Storage scopes are desirable.) That system was not put into production.

Another story has to do with the turret motor in a tank. When the turret stopped rotating the resultant voltage spike would destroy all of the tank's electronics. (Talk about concentrating one's mind!) The temporary solution - since the problem was discovered late - was to buy huge zener diodes from Delco Radio (as it was then called) and place them across the 28 volt line.

Arie,

The nec listing is below. I am unable to 'edit' the coil, element 2.

In 'edit' mode how are the GH and GM cards edited? (The coil is displayed intermittently.)

Is there something specific about using tags 101 and 102 as opposed to 1 and 2?

Thanks - Dan

All,

Can someone explain what is going on with this antenna? There are two resonant points, one at about 4.5 MHz and one at about 6. The first one has a low impedance and the second one has a high impedance. I actually saw this phenomenon with a physical antenna being measured with an 8405a but had did not recall ever hearing it discussed.

Thanks - Dan

Thank you for discussing principles and effects.

Agreed, that the alternator does not produce pure DC, so the voltage
will not be quite as quiet as it is at the other end of the several
feet of wire that connects to the battery positive. (But to paraphrase
Ceeil Moore's question to me, earlier) Do you have any idea,
quantitively how much voltage you are talking about? THe ripple
current in the output of the alternator sjhould be a few percent of the
DC, at most, with some high frequency pings caused by rectifier reverse
recovery. Adding a rather small PI filter is very effective at
reducing all this no a much lower value. And the small charging branch
to the battery cuts the other way, also. If you draw significant
current from the battery, the battery's voltage is held lower than the
alternator voltage by the IR drop of that wire. And that drop lowers

the charge state of the battery.

> Every time you turn on the headlights the noise will get worse if the

> voltage drop on that line.
> If there should be a break in the alternator wire to the battery the
> surge from the alternator will most likely damage the radio.

Now, you may just have hit upon the one factor that trumps every other minor effect. Unfortunately, the most common cause of load dump voltage damage to automotive electronics is caused by a loose battery terminal. So, till you solve that problem, you are not gaining much insurance by moving your connections to the battery terminal.

> The alternator regulator most likely would not be able to handle the
> rapidly changing load of an SSB radio smoothly causing additional
> spikes as it tries to regulate.

Is any radio not equiped with input bypass capacitors? I am skeptical. If this were the case, the radio would not tolerate feet of wire in the power circuit. Do you have a schematic of any DC powered radio that does not show some storage at the DC power input?

Again, we are not talking about powering from an alternator with no battery attached (except for a terminal comng off the battery), only moving the power point to the other end of the battery charging branch wire (that 2 or 3 feet of 10 gauge wire you mentioned earlier (with, possibly a fuse link section in it) so that the average current arrives from the alternator, and only a stabilizing effect on the ripple arrives from the battery through that wire.

> Need more reasons? :>)

Who knows? If you got 'em, I am happy to think about 'em.

I want to thank you, again, for taking time to think (in print) about what is going on in this system and what can go wrong. This has been helpful.

Roy Lewallen, W7EL wrote:
"Long ago, I bought and built a Heathkit SSB mobile rig, and I recall drilling holes in the ends of the battery posts and (gently) driving in some special terminals that came with the mobile supply."

A good idea! Corrosion at the posts can allow transients exceeding the battery voltage. Tapping directly into the posts, clamps the voltage to the battery volts despite other faulty connections. When you try to to raise voltage across a low resistance battery, it maintains its terminal voltage very well.

Automobile radios usually connect to a designated place on the fuse block. This works despite transients because the radio`s current drain is small and relatively constant. It doesn`t step up to transmit. The car radio has inside, an air-wound choke in series with its battery supply and this continues to a "spark plate" capacitor of a few picoFarads to ground, inboard of the choke, to filter out r-f interference and to take the edge off power surges.. For longer transients, an electrolytic capacitor shunts the spark plate.

An electrolytic capacitor is the short-term equivalent of a battery. Instantaneously, the volts across a capacitance can`t change. But, capacitors are imperfect. Their leads have inductance, and the capacitor has series resistance.

In the 1950`s, I bought a Blau Punkt radio for my new Karman Ghia Volkswagen. The radio was equipped with a heavyweight iron-cored choke outside the radio in its power lead. Of course the radio was filtered internally with electrolytic capacitors.

The L-C powerlead network was an effective transient suppressor for a radio that was meant to be connected to a fuseblock.

Problem in using the L-C network with a transceiver is the current drawn while transmitting. Resistance of the choke must be very low not to degrade performance.

Best regards, Richard Harrison, KB5WZI

> their power-supply terminals for a brief moment.

This is an effect that is well worth discussing and understanding,
thoroughly.
The load dump (with battery connected) would be a very slight thing,
if the alternator could react instantaneously to load changes. But
like any feedback control system, it has a maximum frequency that it
can react. The electronic excitation regulator is quite fast at
detecting the slight rise in system voltage following a load reduction
(headlights turned off), but the magnetic field around the rotor takes
more time to decay after the excitation regulator decides to cut its
current. During that time, the alternator ramps its output current
down from what the load curent was before the dump to what it is after
the dump. So there is a few 10s of milliseconds when the battery has
to absorb the extra current. And that pushes the voltage across it up.
The opposite effect occurs (and worse because ocold filaments draw
almost 10 times the normal current) when the headlights are first
turned on. There is also a wiring system inductive effect that adds an
additional but very brief (microseconds) peak to each of those
excursions.

I want to understand why the recommended way is best, all things considered. I see some positives and some negatives, and judged, on balance that the "normal" way was not necessarily the best way. But, the load dump factor may outweigh all the others, if it causes damage. I'm not so sure it does, but this diuscussion is helping me weigh it.

All the principles involved should include only known science. As long as I don't miss anything, the probvlem should be solvable without reinventing electrical principles by experiment. But a few accurate measurements of the voltage spikes at both the battery terminals and DC bus distribution point are probably not a bad idea, in any particular car.

Thank you for supplying an important missing piece of this puzzle.
I would add that if your battery starts to get a little flakey and the
voltage is sagging pretty low during starting, you can have a large
increase in the load dump voltage at the battery, even if you have made
the seperate connections you describe, just because of the increase in
the battery impedance.

One of the most common electrical system problem in cars is loose
battery terminals, and I'll bet not one person in a hundred, that
installs separate leads to the battery, terminates them as you
describe. So when I hear stories of a load dump causing damage, I
always wonder about how clean and tight those terminals were.

Dan, your LD commands are incomplete. You have specified a series RLC in the middle of each of the end tags. You show an R of 0.001 ohms, and an L of 30uH. There is no corresponding series C. What you have is an end inductivly loaded dipole., with floating end segments. This probably accounts for your anti-resonance at about 6 MHz.

Your GE 0 card is ok -- indicating no ground plane -- but you have retained a Sommerfeld/Norton ground description in the GN card. Not that it makes any difference to the final result.

I replaced my original equipment GMC pickup battery with
a Sears Die-Hard with four ternmials. Two of the terminals
are the standard GMC terminals on the side and two of the
terminals are old-style posts on top. I tie my transceiver
to the two posts on top.

Dan, when using the GM card it reassigns the tag numbers, by adding the number in the first field to those cards it moves. This is to avoid confusion. The LD cards, or any other cards, if applicable, should then use the reasigned tag numbers.

Neat idea!

I've noticed that some of the Optima batteries (e.g. the blue-top
dual-application type) come with two sets of battery posts - standard
car-type posts, and smaller (threaded - SAE?) studs. Might be a good
idea to connect radios to the threaded studs, using heavy-duty ring
terminals on the ends of the wires.

Most radios do not have much for DC line filtering in them. Maybe a
500 to 1000 mfd cap if that. With a current draw of around 20 amps for
the typical transmitter 1000 mfd is not much capacitance at 12 volts.

As to the "load dump" problem, when the radio draw swings from around
1 amp to 20 amps at an audio rate I have to believe that the
alternator regulator would have a hard time keeping up and not
allowing overshoot or holes in the supply current.

Alternator filters can help filter out alternator noise but some times
they fail to do so even when the radio is fed directly from the
battery.

I have one ancient but probably still valid reference to alternator load dump. It indicates that it can be simulated by connecting a 6000 uF capacitor charged to 120 volts to the system. The result is a 120 volt spike with a decay time of several tens of ms. (The reference doesn't show the load current or impedance, but presumably this is with a typical automotive load and wiring system.) It also shows how a so-called "'A' line filter" -- an L network of 200 - 400 uH and 1000 uF reduces the peak voltage to a mere 40 volts but with a stretched decay time. The conclusion is that robust automotive electronic devices should be able to withstand this. I got this from an app note for a National audio amplifier IC which was designed to be used in automotive applications and so can withstand momentary 40 volt spikes.

(snip)

If I had a radio that had a 20 ampere power swing through the supply leads at audio frequencys, I would consider it a poor choice to run those power leads more than a few inches without adding some serious storage at the radio end of the wires, just to reduce the IR (reduce peak amps to something closer to average) and inductive drop of the power wires. The same applies to an audio amplifier of similar current draw. It is very common for large audio amplifiers to have serious capacitance at their end of the power wires. This also reduces the peak voltage during a load dump.

If you haven't cut it yet, don't.

Is it insulated wire or bare? If it is bare it is not important. Just get the spool right up there at the end of the "antenna" part of the wire.

I'd just hook it up and try it. If it is insulated wire the supposed loading coil on the end may very well be irrelevant. It won't be radiating and, being at the end, it isn't loading anything significant.

I use my 40M invert Vee on 6M and work several states.

Make a "dipole" out of just OVER 1/2 wave of wire. Then form the center
into a single turn loop and couple it to (bring it near) the loop in the
unit.

Here's another.

I once had a battery with a very slight leak around one of the posts,
and the terminal kept corroding and making poor contact. I took the
terminals lose, cleaned everything with baking soda, rinsed and dried
all the parts then sanded the posts and inside of the clamps to get a
fresh lead surface.

Here is the tip. I coated both surfaces with a film of heavy silicon
grease (Dow 111, or similar) and re clamped the terminals, squeezing
out the excess grease as the clamps tightened. Even though the
outside of the terminals still got visibly corroded the connection
remained perfect till the battery failed a couple years later. I have
pretreated every battery, when new, ever since, and have never had a
connection problem. The grease completely seals out moisture, acid
and oxygen, but is about as easy as air for the lead surfaces to break
through to make perfect contact.

I see that some headlight bulbs now come pre-glopped with a dollop of
such grease to protect the wiring terminals from moisture.

Steve,

The reason I mentioned clipping a piece of wire off the reel is
that" old friend" mentioned in his initial post a half mile spool of
wire. And he was not specific as to wire size.

I was thinking maybe a wooden reel of # 12 or 14.

And yes, if it's small gauge wire on a little spool at the end, it
would act as a bit of end loading, which would have little effect.

But, ya gotta admit, old friend was not very descriptive.

John

WD-40 also works quite well, as it penetrates and lubricates, and there is less mess. I run dual Optima yellow tops in my Wrangler, and a heavy duty conventional (normal maintenance) battery in my XYL's Grand Cherokee and in my Cherokee, and WD-40 has kept corrosion off of the terminal for years now. Works much better than the soaked red and black corrosion inhibiting felt rings. Just a thought...

Keep the bolts tight. Don't forget to run a heavy enough gauge fused wire pair to the rig to make up for voltage drop over your run length (lest you end up with a 30A load dropping the voltage to 10 or 11V and diminished RF output). Your rig was designed to operate as rated at

13.8VDC. With the engine off, you might get 12VDC. With too light a gauge of wire in a long run, you'll see your display dim or go out as the voltage to the rig drops below the minimum required voltage at the radio when keyed.

>Nuff said. I'll keep that in mind next time you
>say a vertical is 24 dB better than a dipole. :-) ....

Well, of course, I've never said any such thing.
But...It is often a large noticable difference.

Mike sed...
>My guess is that it depends on where
>the signals originated from

Thats exactly it. In general, the farther away, the
better the vertical vs the low dipole.
If you don't work long haul dx, the vertical user
may never see much advantage. At night on 40m,
if the distance is less than 1000 miles, often the
dipole and vertical would be about the same.
In my case, I had to get over a 1000 miles to see
much vertical advantage. At 1500 miles, it's fairly
obvious. "appx 2 S units worth". In the long hauls
to VK, JA, etc, often 3-4 S units worth. That will
be a larger increase than your 2 s units noise increase.
Modeling won't tell the whole story in a case like
this. Just ask W8JI about his 300+ feet dipoles
on 160m. In theory , they were supposed to beat his
vertical towers. But , they usually don't on long
paths where the angle is very low.
I once yakked with this guy in Tokyo for a while.
On the dipole at 1kw, I'd be S 8-9... On the
GP with 1 kw, I'd be a solid 20 over 9. And it's
reciprical as far as xmit/rcve. So I'd always be
listening on the vertical if I wanted to see the same
increase on my end.
The only exception would be if I had something
better like a beverage, etc, but that applies more
to 80 and 160, than 40.
Thats the real point of my comments,
not which is better. To me, installing a good vertical
for dx, and then listening on a low dipole to same is
kinda silly being the benefits are reciprical.
Also...Building a good vertical, but not using it for
long hauls is kinda silly too... :/ It's the wrong tool for
working 500-800 miles away. If it's never better than the
dipole in that case, don't fret too much, as it's perfectly
normal.
MK

When I get a battery terminal with the corrosion and oxidation on it, I
sometimes pour a small quantity of Coca Cola on it. Cleans them right
off. I will then put a small amount of conductive grease on it.

Well, of course, you just said it again. :-) The standardized
S-unit is 6 dB. Therefore, "4 S units" over a dipole is 24 dBd
gain for your omnidirectional vertical monopole. (That's ~17 dB
more gain than a three element Yagi has over a dipole.)

Hand tight, not arm tight. If the bolt is tightened too hard it may
cause the terminal to separate internally and ruin the battery.
This is especially critical of terminals that connect at the front.
The traditional post type terminals are better in this respect.

Cecil ... you are out of context [again].

The earlier post referred to long haul DX on the lower bands where a three element Yagi at optimum height is not easily within the realm of possibility for us mere mortals. [Let's see, 1/2 wavelength high on 80 meters is 135 feet, boom length for a three element Yagi at 80 meters will approach 100 feet, You will need a football field of free space and quite a few bucks, and the approval of several engineering firms, the approval of you town building inspector, and the wrath of your neighbors to compete with a simple vertical over a decent ground.] C'mon Cecil!! Cecil ... apples and oranges ... do not enhance your reputation.

Many of us use verticals on 160, 80 and 40 meters simply because they blow the pants off of horizontals on those frequencis for long haul DX.

The grease isn't conductive. But the normal contact pressure squeezes
it out of the way, and the metal parts touch, normally. It just
surrounds the contact points with an oxygen and moisture barrier.

Any translucent (not filled with Teflon or mineral particles) silicone
grease will work. I have some GE dielectric silicone grease and
several silicone vacuum and O-ring greases I have used, successfully.

I bought my last couple batches from eBay. E.G.

I have 26 runs of 60' insulated (#14 THHN), radials on the surface, pinned down with lawn staples beneath an 80m inverted L. The measured efficiency of this particular arrangement is showing approximately 83%. How much more or less efficient bare wire might be (and no one I trust has ever maintained that there is any advantage whatsoever to bare copper vs. insulated radials on or in the shallow ground), is a question I have not had any interest in looking at.

I'm not about to rip them all out and put down bare copper to see if the efficiency changes, and can think of no other way to answer the question. Of course the absolute value of efficiency is a function not only of the number of radials, but the quality of the earth they are laying on, so YMMV.

You can also find silicone grease at stores that sell plumbing supplies. I've gotten it at Home Depot. It's probably a good deal more expensive than eBay, but a little goes a long way.

1081. Verticals versus Horizontal Dipoles

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-31 20:53:53 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <droip1$o4l$1@nwrdmz03.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 64692

There is much discussion about the relative merits of the simple vertical versus horizontal dipole antennas.

Their radiation patterns are well known. They are very broad in both the vertical and horizontal planes. Both have have a null.

We need consider only the broadside, maximum, radiation from a dipole.

Most of the arguments can be settled by considering the elevation angle of the path taken by the radio wave between the transmitting and receiving stations. Followed by a little elementary geometry or trigonometry. For present purposes a flat Earth can be assumed.

At an elevation angle of around 45 degrees the strength of radiation received from vertical and horizontal antennas are about equal. (This has nothing to do with Eznec take-off angles.)

The heights of the Ionospheric reflecting layers are -

E-layer = 70 miles, daylight only.
F1-layer = 140 miles, occasionally, in daylight only.
F2-layer = 190 miles, night-time.
F2-layer = 250 miles, in daylight.

From flat-Earth geometry, at an elevation angle of 45 degrees, the distance between transmitting and receiving stations is twice the height of the reflecting layer. Therefore, at this distance the received signal strength can be expected to be about the same from both types of antenna.

As the elevation angle decreases, the distance increases and radiation from the vertical antenna increases. The radiation from the dipole decreases. There is an extra propagation loss due to an increase in radio path length but this equally affects radiation from both antenna types.

As the elevation angle increases towards the vertical, distance decreases, radiation from the dipole increases and radiation from the vertical antenna decreases in strength. The radio path loss decreases but the difference in pattern between the two antenna types is maintained at the receiver.

With a spherical Earth, in daylight, using the F2-layer, at elevation angles around 5 degrees, one-hop distances of 3,500 miles can occur. With two hops, at angles of around 12 degrees, distances of 5,000 miles can occur.

For each additional hop there is loss in the layer and loss in the reflection in the ground. Some parts of the radio path may be in daylight and others in darkness. More than one layer may be involved. Muli-path distortion occurs. Peculiar things happen and much depends on frequency.

The low-angle performance of a half-wave dipole, even when radiating broadside towards the receiver, is very poor in comparison with a simple vertical.

On the other hand, a simple vertical does reasonably well when working just across county because of the short propagation path, almost straight up and down again, or even via the groundwave for very short distances.

Reg, G4FGQ.

Source record: 64695

Whoever authored "AM Loop Antennas" attached to Chuck Olson`s posting wrote:
"A spiral loop is least sensitive to signals received in its plane."

Nonsense. Spiral, edgewound, or whatever, any loop antenna which is small in terms of wavelength is sensitive to signals within its plane, and insensitive to signals broadside to its plane.

My authority is Kraus` 1950 edition of "Antennas", page 160, Fig. 6-6.

The plane wave arriving broadside to the small loop tends to generate currents in the same direction in all sides of the loop. The sides of a turn in the loop are connected in series. So, the currents in opposite sides of the loop tend to add to zero when the wave sweeps the loop from broadside.Time of arrival and phase are the same on both sides of the loop from broadside.

Best regards, Richard Harrison, KB5WZI

1085. Why did this work (160m antenna)?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-31 22:14:38 UTC
From: hasan schiers <schiers@netins.net>
Message-ID: <drongf$d6v$1@news.netins.net>
Source record: 64696

Necessity being the mother of invention, bit me. Last weekend was CQWW CW on 160m. I stumbled on it and had no 160m antenna. I have a terrific performer for 80m, an inverted L with 33, 60' radials stapled on the ground. I also have a Carolina Windom 80 at 42' fed with perhaps 100' of RG8x.

Since it was a cw contest, I figured, brute force stuff with my tuner. Very interesting results.

I tried the 80m inverted L, feeding just the center conductor, and also tying the shield and center conductor together ...both cases feeding it as an end fed wire. I got no band noise and very poor signals, but what the heck, I worked 10 or 15 stations who were running S7 or better in spite of things. I could tell I wasn't being heard very well. (I was also running about 500w output).

Then I tried the same trick with the CW-80. I fed the center conductor only...band noise jumped up to S-3, signals were amazingly loud, and I started working everyone I could hear...first call. It didn't matter how weak they were, I got answered immediately. I worked 44 states, France, and two stations in Bermuda. My question: What is this antenna configuration and why is it working so well, especially relatively low angle stuff like France and Bermuda, West Coast, etc. I don't get it? (Feeding both shield and center tied together, or feeding it "normally" did not work as well as just feeding the center conductor)

This is an OCF Dipole, 85' on one side and 51' on the other. I have no idea which side of the dipole was fed by the center conductor of the coax. My coax runs underground (5' below the ground for 55' to the tower base), and then up parallel to the tower (5 feet from the tower) for the 40' or so the CW-80 is in the air). This really shouldn't work very well, yet it does. VSWR bandwidth seems consistent with a somewhat efficient antenna (about 40 Khz before having to re-tune the tuner.

I'm at a loss to explain why it would seem to work so well as a DX antenna for 160m. Pleased, but surprised. Any theories?

Am I somehow shunt/gamma feeding my tower?

I also had no tuner arcing, no rf in the shack, no RFI in the hi-fi, ...zippo...all the RF appears to go where I would like it to, but I have NO idea why. I prefer to understand things and not just rejoice in my dumb luck. Ideas?

1086. Re: Vertical ant gain vs No radials

Newsgroup: rec.radio.amateur.antenna
Date: 2006-01-31 22:37:24 UTC
From: hasan schiers <schiers@netins.net>
Message-ID: <droor5$f8h$1@news.netins.net>
Source record: 64697

If you have decent soil, 32 radials of the length you specified, will be quite adequate and adding the number indicated by your friend is just a waste of effort and money. Here's a relatively simple (if not completely foolproof) way to tell if you have enough radials:

If you know the theoretical radiation resistance of your vertical over a perfect ground: measure your current input impedance (at the antenna feedpoint) with your current number of radials.

You can find the theoretical radiation resistance of your antenna by looking up short monopoles in the ARRL Antenna handbook...Let's say on 40m, your HF6 is 28 ohms (it's shorter than a full 1/4 wave, so it will be somewhat lower than the 37 ohms of a perfect quarter wave vertical) The shorter the radiator, the lower the radiations resistance and you can read it directly from a graph in the book noted above (or in Devoldre's Low Band DX'ing...can't recall which) (or you can get it from using one of Reg Edwards programs). Anywho, let's say it's 37 ohms.

Now you measure the input Z of your configuration. Let's say it measures 39 ohms. Your efficiency is 28/39 or 72%. If it were to measure 35 ohms, your efficiency would be 80%. You can convert this all to dB loss and you will be able to see if your current 32 radials are enough to make you happy. I found 26 radials that were 60' long were enough to give me better than 80% efficiency (actually that number started to happen between 12 and 16 radials, but my soil conditions are very good).

This way, you take most of the theory and speculation out of things. Use an MFJ-269 or some-such and you can do all the measurements yourself. I'm betting you will find your efficiency better than 70%...also keep in mind you have some additional losses from your vertical being a multi-bander, so the efficiency I'm referring to is based on a single band vertical with no additional loading/trapping/stubbing losses.

In short:

1. Find out what the Radiation Resistance of your shortened antenna should be.
2. Measure the input Z at the antenna of your actual antenna/radial field is.

Divide 1 by 2, convert to percent....a "rule of thumb" measure of efficiency of your system has been obtained.

If you radial field were perfectly lossless, 1 would equal 2. Every ohm above the theoretical radiation resistance of your antenna that you measure is "loss" .

Have fun.

This rather oversimplified analysis overlooks an important factor. The field radiated upward from an antenna seen at long distances (that is, the sky wave as contrasted to the short-range surface wave) consists of a vector sum of two components: one radiated directly, and one which is inintially radiated downward then reflected from the ground. The ground reflection alters both the magnitude and phase of the reflected component depending on ground characteristics and the polarization of the wave. At low angles, horizontally polarized waves are reflected very well even when the ground is quite poor; vertically polarized waves react differently. The resulting fields can fairly easily be calculated manually if desired using simple geometry, equations for reflection coefficient which can be found in Kraus and other references, and vector addition. One thing you'll quickly discover is that the field from a vertical does NOT monotonically increase as the elevation angle decreases, but decreases below a moderate angle determined by the ground characteristics. EZNEC (including the free demo) and other modeling programs clearly show this important effect.

Reg:

Your simplistic analysis disagrees with my 50 years of operating local contacts on 75 meters here in the southern US. Practical verticals are universally 10 or more dB poorer than dipoles for local contacts, no matter what the other variables. The very best quarter wave 66 foot vertical with 365 radials is about equivalent to a dipole lying on the ground for 0 to 250 mile contacts on 75. Forty meters performs a little closer to your argument, but not much. Among long time local ragchewers, verticals are considered to radiate equally poorly in all directions.

The NVIS nonsense also enters here. I have thrown back at the "proponents" of NVIS that elevation angles of 45 degrees or less hardly qualify as NVIS (properly NHIS, maybe?) but they continue to misuse common English to further their specious arguments.

By the way, how much of the UK is within 500 miles of your QTH? I have to exceed 500 miles just to get out of the state of Texas.

Looks to me like there is a bug in the geometry editor "Create Helix"
command, as I have also noticed the same problem. I sure makes for some
really messy looking code. The helix also appears with the axis normal to
the edit page. Have not figured out how to rotate it yet. Whoever wrote
this interface program did a great job, but seems a heck of a lot easier
just to work at the card level.

Thanks. That was wondering if that was the case. Every once in a while the editor converts all my segments into wires. All of a sudden the card file will jump from a few cards with segments to dozens of cards with one segment. This is what the helix command does. It could be the same root cause??

Generally the editor is really easy to use for wires. Have you used the select group and Control M features yet? They make changing a group of wires straight forward.

I wonder about the accuracy of the power calculations. They seem too high.

I am experimenting with modeling loaded dipoles versus folded dipoles, extended W's or M's.

Thanks - Dan

I have acquired an old tower. I was told the brand is Wilson but I
can't seem to find any information on it. I have photos and I 3D model
I drew here....
http://cdw.homelinux.com:8087/stuff/Tower/

If some one could tell me where I can find specs on it and what kind of
wind load it can handle, I would be grateful.

Note you have to down load this free program to view the 3D model

Hi Hasan,

You tied the shield and center conductor together - isn't that a short
circuit for the inverted L?

> I got no band noise and very poor signals, but what the

Sounds like a short.

>heck, I worked 10 or 15 stations who were running S7 or better in spite of

>for 160m. Pleased, but surprised. Any theories?

One theory is you could have done a whole lot better - but that is
pure speculation. Another theory is you could have done a whole lot
worse - that doesn't need to be proven because we can all achieve
that.

>Am I somehow shunt/gamma feeding my tower?

Could be. Could be so lossy as to defy SWR too.

>....zippo...all the RF appears to go where I would like it to, but I have NO
>idea why. I prefer to understand things and not just rejoice in my dumb
>luck. Ideas?

For one, I've seen a number of posts recently proclaim the
accomplishments of DX, Low Angle antennas. The two are not
necessarily tied at the hip. It is all predicated on the bank shot
against the ionosphere, and a low angle could as easily end up in the
drink as it could in Lower Slobovia. And Versa Vice, a high angle
(call it 30 degrees) could as easily hit Ulan Bator as it could drill
into Pike's Peak.

True, a high angle is more susceptible to multi-hop losses, unless it
is bouncing over the Pacific on the first two caroms. Without a valid
propagation model tied to the radiation distribution characteristics,
calling an antenna a low Angle, DX performer is a mighty flight of the
imagination.

Short answer: a propagation modeler tracking real time results will
answer more questions than attaching claims to simple monopoles or
dipoles.

I've used WinCAP with a highly distorted antenna response curves to
probe launch angles. WinCAP comes with sample antennas, like the
common quarter wave vertical. I've edited that file such that output
at all elevation angles, except one, are severely reduced. Basically
a one degree height elevation lobe set at one particular angle (for
the sake of argument, a 5 degree launch angle, ï¿½ï¿½ degree). When it
reaches Europe, the footprint floods France.

Now, we know that such an antenna is nigh on impossible to build for
HF, and the common vertical is going to launch very useful power over
a far greater span of angles. The upshot of this is that instead of
that ï¿½ï¿½ degree, we take the typical ï¿½15 degrees around a typical
launch angle of 20 degrees, and you cover a lot of ground at the other
end * IFF * the Ionosphere will support them. And just as much power
will probably hit France even though we've quadrupled that "low"
launch angle FROM 5 degree launch angle, ï¿½ï¿½ degree TO 20 degree launch
angle ï¿½15 degrees.

Hi Richard,

Of course, when the inverted L was fed with both shield and center conductor shorted, that is a short. But I also tried feeding just its center conductor..and it was poor, as it should have been. I'm not saying that the CW-80 center conductor only, brute force tuned was a great antenna, just way better than I had any right to expect. It's not like 160 is like 10m, where, when the band is up, nearly anything works. 160 is notorious for exposing poor antennas.

In any case, without a legitimate reference antenna, I am limited to "how well do I get answered and at what distance" analysis and that's what I tried to provide.

A test I would like to do sometime is to get a KW-80 trap, put it on the end of the 80m L and extend the wire out for 160m resonance. Then I would have a 2 band inverted L and that would be a reasonable reference antenna. What has kept me from this is I had a hard time finding the KW-80 traps...they were out of stock. My other concern is since the 80m inverted L works so well, I don't want to do anything to ruin its performance. (It's also hard to get motivated to go out and do the raising and lowering and tuning in the middle of winter, yet if I don't do that, there won't be much I can do to evaluate the trap's effect on either band.

I was trying to get "something" for nothing with the CW-80 trick, and succeeded beyond my wildest expectations. Nothing about my situtation could allow anyone to duplicate what is happening here. Too many variables. I just got dumb lucky, and THEN I get curious. I still think this arrangement should not work very well, and that just isn't the case. The goal was to get on the contest and make contacts as if I had a "good" antenna. Anyone who does contesting knows what a "good" antenna feels like as you call stations and listen to those being called. It is so easy in a very few minutes in a busy contest to accurately conclude: this antenna is crap. I couldn't do that and was mystified as to why not.

Either this antenna was working as some sort of kludgey inverted L or somehow the tower was getting excited, or both. Whatever set of fortunate circumstances obtain, if I were to have put up a "proper" antenna for 160 and gotten the results I did (and if those results were/are repeatable), I would have said, "This thing works pretty well." I then became very curious, and that is all. As you noted, without a reference antenna, a real assessment is impossible. However, how the antenna performed on the air in a situation that is well understood (contest environment) made for some raised eyebrows on my part. Rarely does "loading up what is laying around" work. In this case it did. Antennas and propagaton obey the laws of physics. I'm just wondering which ones apply and in what manner for this particular

"arrangement".

I'm left with the question, just "what kind of an antenna" is this, or does it "resemble", that would perform as well as it did.

Radio signals and how they propagate still resemble "magic" at times, yet no one in their right mind would build the mess I was brute forcing my RF into, nor would I recommend it. At the same time, if one just "has" to get on the air in a hurry, my experience might prove useful. If there is one thing I learned from this it is don't dismiss something out of hand without trying it (if there is an urgent need). You may get surprised. Then if it works well, try to explain it later (if you are curious...and I am.)

Thanks for your comments.

Opinions of the many individuals depend on geographic lattitude, World population densities, what bands happen to be favourites, G5RV's and how much money there is in the bank. Let's try to remove these distracting factors.

I'll put it in somewhat different "simplistic" terms.

Everything else being equal, the deciding factors are geometry and trigonometry. The performance of a dipole is better at elevation angles greater than about 45 degrees and the performance of a vertical is better at lower angles. That's because the vertical and horizontal antenna types are oriented at 90 degrees to each other. At elevation angles around 45 degrees performance is about the same for both types.

The ground path distance corresponding to 45 degrees depends on height of the ionospheric reflecting layers. Layer height depends on which layer, mainly E or F2, day or night, summer or winter, and the solar sunspot cycle.

(None of these important factors are taken into account by antenna modelling programs. Propagation prediction programs DO take them into account but, with them, geometry is also an essential factor.)

The range of distances at which vertical and horizontal antennas have similar performances in daylight is from 140 miles (E-layer) to 500 miles (F2-layer), which falls to 370 miles at night.

But what decides whether a transmiiting antenna will be used or not is NOT the distance to the receiver - it is the MUF (maximum usable frequency)

The MUF is geometrically-derived which increases with distance and with a decreasing elevation angle. It also changes with geographical lattitude and sun angle. With the F2-layer the MUF can increase by 3 times the vertical critical frequency Fcrit. Thus, by using a vertical low-angle antenna there are more bands and potentially more listeners available.

Fcrit is the highest frequency which is reflected from a layer at vertical incidence. At higher frequencies the wave passes straight through. The MUF for high radiation angles and short distances is therefore low. It does not increase very fast as the radiation angle falls. It varies with night and day and the solar 11-year cycle. For the E-layer in summer daylight Fcrit is about 3.5 MHz. For the F2-layer in summer daylight it is about 6.5 MHz and about 5.5 MHz at night. On winter nights Fcrit for the F2-layer is about 3.5 MHz.

Fcrit and high angle MUF's are subject to variation due to solar activity. But in general only the 80m and 160m bands, and sometimes 40m, are open for short distance rag-chews. This restricts the advantages of high-angle horizontal dipoles.

Finally, a horizontal dipole radiates best when broadside on. Unless it is rotateable it has weaknesses in its service area.

If I had to choose, I'd always choose a half-wave 80m vertical in preference to a half-wave dipole.

Reg.

1098. Re: editing 'helix' construct with 4nec2 graphical editor

Hello Frank and Dan,

red your discussions with interest. Some few answers:

> The helix also appears with the axis normal to the edit page

Yes, you are correct. To get another orientation select XZ, YZ or XY
plane,
before creating the helix.

> Have not figured out how to rotate it yet

Select all segments using Ctrl+A or select the required segments by
drawing
a rectangle around them and select 'Edit->Rotate/Move wires' on the
menu-bar.

> Every once in a while the editor converts all my segments into wires. All of a
> sudden the card file will jump from a few cards with segments to dozens of
> cards with one segment

Hmmm, do not have an explanation for this yet. Did you change the
segmentation-
density between subsequent edit sessions ?

> I wonder about the accuracy of the power calculations. They seem too high.

Please, let me know if you think you found an error. I would very much
like to
hear this,

Thanks for 'testing' and remarks,

Arie.

Hi Dan, hopefully Arie is following this thread, and he may have the contacts to resolve these questions. I have not done anything with the editor concerning wires. Your comments make me think I should take a look at it.

What do you mean by power calculations? The only power info I am aware of is the total radiated power. This power is a little misleading in that it does not consider ground absorbtion, and is only valid above a perfectly conducting ground. The e-field Vs angle info is accurate for all conditions. The true radiated power can be obtained by summing these data over a hemispherical region.

Hope you get some correlation on the loaded dipoles when compared with the 8405 measurements.

Frank

Cecil, W5DXP wrote:
"I`m putting a vertical back up for transmitting and will probably receive on my horizontal dipole."

If your grounded tower is near 1/4-wavelength on your favorite band, why not shunt-feed the tower and use it as your radiator?

On the other hand, if you want to support another antenna and eliminate radiation from the supporting tower, outrig a wire from the tower top, hanging parallel to the tower, and connected to the tower top through an L-C network tuned to make current in the outrigged wire equal ond opposite that in the tower. The balanced currents cancel the tower`s radiation. This may be tedious for frequency hopping, but it works.

Best regards, Richard Harrison, KB5WZI

Hi Hasan,

Maybe I just cannot visualize this. The inverted L is fed at the
bottom (at ground level) of a vertical rising wire that at some
distance up meets a horizontally running wire (or the same wire just
takes a horizontal bend out). It is fed with a coax whose shield
connects to a radial field (this is how I am interpreting your
antenna's description that I read, perhaps this is in error).

You also have an OCF Dipole that you have played with, but both
descriptions are woven so tightly together I will try to sort out the
jumble of descriptions.

All former connections remain as they were, but what I read next is
that

1) at the feed point you short the coax center conductor to shield,

OR

2) you short the coax center conductor to shield in the shack.

If (1), then that is simply a dead short which is confirmed by your
report "I got no band noise and very poor signals"

If (2), then you have a lot of RF being pumped directly into the
ground as per your description " My coax runs underground" and you
have left unsaid what you use for ground in the shack.

You also have an OCF Dipole fed with another coax (another
presumption). You feed this:

1) in the conventional way, as a dipole;

2) just with the center conductor (against shack ground?);

3) both the center conductor and shield (against shack ground?).

(1) results in no particular performance to write home about;

(2) or (3) presents far more DX opportunities and clearly more signal
than (1).

>In any case, without a legitimate reference antenna, I am limited to "how

By your description, you already have a solution. There is unlikely
to be a better one than:

>I was trying to get "something" for nothing with the CW-80 trick, and
>succeeded beyond my wildest expectations. Nothing about my situtation could
>allow anyone to duplicate what is happening here.

Strictly speaking, yes. However, the general solution you stumbled
across is fairly typical advice here - if we are speaking of the OCF
Dipole being fed with its elements shorted (or otherwise one half of
it as you seem to see it).

The only improvement I would see is to break the OCF Dipole's coax at
ground level and feed THAT shorted together with the coax coming from
the shack (the newly broken end). Attach the short to the center
conductor, and the shield of the coax from the shack going to the
ground field. When you want to use the OCF Dipole in the conventional
way, open the short, remove the ground and connect in the conventional
way. This could be reduced to a couple of switches at ground level.

Otherwise, what I see in the (2) - (3) OCF Dipole feed situation
above, is that you are also feeding a massive, lossy capacitor
(ground) along the way to the OCF Dipole. The (2) - (3) OCF Dipole
feed situation is simply a top loaded vertical which may enjoy some
harmonious relation with the tower in proximity.

Another possibility arises from the tower. If it is guyed, insulate
the guys about 1/3 their length down from the top, but make sure they
are connected at the top (Top Hat). Feed with a gamma match against
your ground field. The gamma wire will probably trace the same path
as your OCF Dipole line (2 to 5 feet out from the tower) and you will

need a few hundred picofarads to tune.

Richard, you are correct - - thanks for spotting that - - the edge-on view of the loop in red should be in line with the "node" direction rather than in line with the "null" direction. I hadn't looked very carefully at the text since I was more interested in the links section at the end, which I felt might be a good resource for Eric.

Richard, thanks for your patience. I'll try to be more concise, as it is much simpler than the comments we've exchanged so far.

I tried 2 antennas in different configurations:
==========
1. Feeding the center conductor of the Inverted L. Coax runs underground 50' or so, then connects to my radial plate/coax connector. That arrangement stunk. Band noise S-0, strong signals S-7. Worked about 10 or 15 stations.. Lots of calls unanswered. VERY PREDICTABLE, a poor performer to be sure.

2. Feeding the Inverted L conventionally...same result as 1 above. Perfectly predictable.

3. Shorting the Coax at the shack end and feeding as a random wire ....stupid idea...dead short....I didn't even load it, there were no signals to listen to, OF COURSE. (You have to understand, I was in a hurry and not thinking very clearly.)

END OF Inverted L Experiment.
==========
Begin CW-80 Experiment: (OCF Dipole with Line Isolator) up 42'. 85' one side, 51 feet other side.

CW-80: 50' underground coax, then about 45' of vertical coax to the feedpoint of the CW-80 (OCF)

1. I did not feed it conventionally, as I didn't want to chance heating up the "Line Isolator" located 22' below the feedpoint of the OCF. In other words, I didn't just plug the CW-80 coax into the tuner and try to tune it up on 160. I was afraid this might cause the "Line Isolator" to fry (the one located 22' below the feedpoint of the CW-80)....that is how the CW-80 is constructed...it comes with the line isolator, and you attach your coax to the line isolator. Shack > Coax, abt 95' > Line Isolator > 22' Coax > Feedpoint.

50' of the 95' from the shack to the "Line Isolator" is underground in a plastic pipe (along with 3 or 4 other coax cables)

2. Fed the center conductor of the shack end of the coax as a "random wire". I just pushed the center conductor into the coax connector on the back of the antenna tuner and made sure the shell was not connected to the tuner.

The worked rather well, as my description earlier details. I'd call this combo a winner. As I said in my prior post, if I had built an antenna to work on 160 and got the results I am getting with this option, I would have concluded that I had a "good" antenna. (For the real estate in use)

3. Shorted the center conductor to the shield and fed that to my tuner center conductor output as a random wire. (Thus using both the shield and the center conductor in parallel as a "random wire". This configuration did not work any better (and perhaps slightly less band noise) than solution 2 above.)
==========
The full layout of the tower and two wire antennas:

Tower is 48'. At 46' or so, I have a 10' metal horizontal cross boom for pulleys (see below) At 50' I have a 6 element log periodic for 13-30 mhz. at 60' I have a dual band homebrew J-Pole for 2/70cm. So the total vertical height is about 65', with whatever loading the LP has. The LP only has a 14' boom.

So, I have a 48' tower with a 10' cross boom at the top section holding a pulley on each end. One pulley has the CW-80 OCF feedpoint on it with coax hanging down 5' away and parallel to the tower, to ground level where it goes into the pipe, underground for about 50' to the shack.

The other pulley on the other side of the cross boom holds up my 80m inverted L...about 42' vertical and then a sloping wire to complete its proper length for 80m. (about 25' or so). Its feedpoint is about 6" above ground level above a radial plate with 33, 60' radials made of #14 THHN (insulated) wire, stapled to the lawn. The vertical wire is about 5' away and parallel to the tower (on the opposite side of the tower from the CW-80 OCF.

Hopefully, this clears things up.

The only experiment I'm left with is adding a KW-80 80m trap to the 80m inverted L and then adding sufficient wire to get resonance on 160. I take from your prior comments that you don't think this arrangement will work any better than the "dumb luck antenna" I stumbled into. I'm inclined to agree, as the 42' vertical section of the Inverted L isn't all that great for 160...but one never knows.

I just don't want to compromise the current performance of the 80m Inverted L...it is doing a wonderful job on 80m. I worked England on cw and S92RI in Sao Tome & Principe Is.on SSB, first call. (West Africa). Making repeated observations comparing the CW-80 (conventional feed) and the Inverted L has shown the Inverted L receive strength about 2 S-units better on paths beyond 1000 or 1500 miles. On real DX paths, the Inverted L is quite a bit stronger than the CW-80. Of course, the noise level on the Inverted L is higher than on the CW-80...all the time. It is rare that I have to listen on the CW-80 and Transmit on the Inverted L....but it has happened. This inverted L project has been one of my most enjoyable projects in ham radio in years. Measuring the input Z as I went from 0,2,4,8,16,26,33 radials was a rush, as was running 2:1 vswr bandwidth changes with each radial increment increase. The results were downright text book! Falling input Z, decreasing 2:1 vswr bandwidth as radials were added. Nice predicatable slope.

When Reg gave me his rule of thumb equation for radiation resistance of an inverted L, that allowed me to begin calculating efficiency based on

feedpoint Z...further fun. And, to compliment Reg, I found two other sources for the calculation of Rrad of an inverted L and they both agreed with Reg within an ohm (about 25.4 ohms predicted)...although their formula was different. Reg must have some sort of magic reference library, or he has made a bajillion measurements. No matter, his formula worked and was confirmed by two other sources. So far, I've been able to lower my input Z to about 29 ohms, so my efficiency (I know... a crude measurement at best, but better than nothing) is 25.4/29 or 87%. I'll be adding an additional 17 radials when weather and motivation improve, for a total of 50 radials. I'm not expecting any real improvement in performance, but I have the wire, I have the plate, I have the ss hardware, and I have the lawn staples. If I break 90%, I'll be very surprised.

Again, thanks for taking the time to chat about my two projects.

73,

Hi Hasan,

You say the Inverted L works on 80, so we will leave that alone.

Aside from the odd tail (the drop to the choke), yes you do stand a
real chance of Common Mode current due to the deliberate imbalance
(the Off Center of the OCF Dipole).

However, when you are driving both sides shorted (or even just one,
singly), the choke is going to be engaged and become a loss (this may
be one reason why it matches well). This is the nature of choking
afterall. If it is built to present enough Z in the 160M band, it
could even disconnect the top hat (but that is not what you are
reporting). Something about the "Line Isolator" seems to lack a
choking action (which further suggests it doesn't choke and it doesn't
isolate).

Anyway, low 160M dipoles nearly always have dismal reports here. On
the other hand, strapping both side of the driveline together and
feeding that, as you say "random wire," often brings good results if
the dipole is high enough. Low/High? and for the same height for the

same band? The kicker is one is horizontal polarization, the other vertical. That height is too low for horizontal, but suits vertical polarization better.

>3. Shorted the center conductor to the shield and fed that to my tuner

Perhaps because with a hot shield, and ground so close for so great a distance....

>==========

Sounds like a perfect platform for a top loaded 160M vertical. Take a cue from your recent success with that polarization and work with what nature has given you.

>160...but one never knows.

It's a 1/16th wave tall (or a quarter of a quarter), but top loading will boost that to maybe 1/12th wave tall - still no great shakes. However, experience has shown you were surprised with a "dumb luck antenna" that has no more advantage in height. Thus it follows that even as short as that still brings reward.

The long and short of it is that there is probably little to gain (pun intended) with more work. I would still suggest moving the feed point away from the back of your tuner, and:
>>The only improvement I would see is to break the OCF Dipole's coax at
>>ground level and feed THAT shorted together with the coax coming from
>>the shack (the newly broken end). Attach the short to the center
>>conductor, and the shield of the coax from the shack going to the
>>ground field. When you want to use the OCF Dipole in the conventional
>>way, open the short, remove the ground and connect in the conventional
>>way. This could be reduced to a couple of switches at ground level.

The absolute long and short of it is: "don't look a gift horse in the mouth."

Hi Chuck,

The lawn staples are from DX Engineering (as was the beautiful radial plate with bulkhead coax connector).
They are about 6 inches long, a rectangle, maybe 1 inch wide, and heavy enough that you can pound them in with a hammer, as long as your soil isn't concrete. Sold in packages of 10 or 20, I think. Quite reasonably priced. I only have one staple per wire now (doing it in the middle of winter made me move quickly between ice and mud patches). I'll put down a staple every 10' or so when things dry out.

Google DX Engineering and you will find there web site. From there it's pretty easy to find stuff.

Finally, a horizontal dipole radiates best when broadside on. Unless
it is rotateable it has weaknesses in its service area.

If I had to choose, I'd always choose a half-wave 80m vertical in
preference to a half-wave dipole.

Reg.

all antennas are a trade off
no antenna is better than some other antenna at everything
what is better can be very subjective

can you make it, do you half to buy it, can you aford it,
do you have room for it, half to hide it from the neighbors,
how high can you put it up, any big trees handy for hanging wires

must your antenna work all bands from 80 to 10
or just be great on one or two bands
what band, what use, rag chew, dxing, contest, what kind of test
Cal. qso party is quite diffrent from CQ wpx

80 meter 1/2 wave vert is 130 ft high how many ops
can put up a 130 ft vertical in their back yard

store bought ground mounted multiband verticals
good ones are expensive, nearly none are close to 1/4 wave high,
and a good ground system is a must

always lusted after a high gain high tower vert
but they now sell for about 875 dollars u.s.
and
my xly is not about to let me tear up her flower gardens
to lay out a ground system

on 75/80 out to 750 miles a 1/4 wave vert
is about as good as a dummy load

good in the clear, big vertical is a great dx antenna
but if you are going to dx with it on 160, 80, or 40
you are going to half to also put up a receive antenna
verticals are horrid receive antennas on low bands
as they pick up every bit of man made qrn

20 meter ground plane feed point at 35 or 40 ft is a wonderfull dx
antenna

lower bands horizontal pattern of horizontal half wave dipole
do not come in to play unless at least 1/2 wave above ground

dipole has been the most popular amateur radio antenna for over 60 years
reason
easy to make, easy to put up and keep up,
for most general purpose use work very well

which is better dipole or vertical, is a question that has no answer

best antenna is the one you have up right now

I am attempting to setup a 802.11b bridge between my location (siteA) down the powerlines but off to the right NLOS (siteB) roughly 1 mile away. Now their is nothing between the powerline and siteB except it is off the powerlines to the right by about 20-40 feet. No trees, hills or any other unforeseen obstacles other than I simply cant see it due to the location. I guess the easy way to explain the setup is picture a L. I have successfully been able to broadcast my signal in reverse from siteA down the powerline even further than siteB but it was a strait shot and also was NLOS due to a house being directly in front. This was using a 24db parabolic grid antenna. My question and what I am trying to get my head around is if I could get by with just a standard wireless router without any external addon or booster antenna at siteB. Common sense tells me that even though its shaped similar to a L as long as the signal coming off siteB is present at the end of the powerline then I should be able to pick it up from the grid antenna. I plan on trying it this weekend but I am hoping someone can elaborate on this before I get my hopes up to much.

1111. New program - Antenna Counterpoise.

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-02 02:05:43 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <drrpdn$5g4$1@nwrdmz03.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 64721

A coil-loaded counterpoise at a low height above ground is used to provide an artificial ground for an antenna when, for some reason, a true ground connection is not possible or there is not enough space to erect a full 1/4-wavelength horizontal wire.

The principal effects of low height are a loss resistance induced in the wire from the ground, and a reduction in propagation velocity along the wire.

A counterpoise can be considered to be an artificial ground. Its input resistance at resonance is equivalent to the input resistance of a true ground connection but its resistance will never be as low as a good ground.

To provide a lower input resistance three or four counterpoises can be used in parallel. Or they can be resonant on different bands.

New program C_POISE estimates the performance of a single coil-loaded counterpoise. The number of turns on a coil of given length and diameter needed to resonate a low wire to 1/4-wave resonance is calculated. The input resistance at resonance is also estimated..

All program output data is approximate due to the very low height of the wire above ground and uncertainty in the characteristics of the soil or whatever other materials may be under the wire. The wire may be allowed to rest on the ground surface but uncertainty will be at a maximum. It will nearly always be needed to prune the wire length for resonance. Or when the wire length is fixed the coil turns may need adjustment.

When wire height exceeds wire length accuracy is much improved. Input resistance at resonance will be fairly small. Working Q will be high and the counterpoise will behave as a short antenna. For precise resonance the wire will still need pruning.

Download program C_POISE in a few seconds from website below and run immediately.

Source record: 64722

Greetings all.

I am interested in suggestions for a compact and portable antenna for my Rockmite 40m QRT xceiver. Something I can pack easily is ideal, optimized for 7.040. Besides the baside wire dipole, anyone have some suggestions?

Arie,

Thank you. I tried your suggestion to capture all the segments in a helix. The first problem is "the edit option" is not always available. Sometimes the edit is not available. Have you seen this? Anyway, it is not possible to use edit. Control M does not work either.

Dan

Bryan-

I don't think the power line has anything to do with your signal.

One technique that has been used to get around corners, is use of a
passive reflector (metal grid?), sometimes called a "billboard". It is a
lossy method, but not nearly as bad as what you seem to be trying to do!

The structures between sites may not block all signals. With 24dB at each
end, there might be enough signal to complete the link if two parabolic
antennas were pointed at each other.

Your greatest chance of success would be to erect a mast at each end, and
mount the parabolic antennas high enough to shoot line-of-sight above any
obstacles.

How do you measuring success? One program that works with a wireless
card, is called Stumbler. (I have the Macintosh version.) It detects
wireless hotspots, and gives an indication of signal strength.

Fred

Reg,

Thanks. I assume the coil is located next to the feed point?

In the case of a single ground radial what can you say about the radiation pattern?

Thanks,

Dan

1116. Re: Verticals versus Horizontal Dipoles

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-02 07:52:30 UTC
From: nm5k@wt.net
Message-ID: <1138866750.041474.65870@g49g2000cwa.googlegroups.com>
Source record: 64727

>If I had to choose, I'd always choose a half-wave 80m vertical in
>preference to a half-wave dipole.

In general, I'd prefer the dipole on 80m. But I work mostly
close in within say 600 miles on average. A dipole will smoke
most verticals at those short distances. If the dipole is at least
30-40 ft off the ground, it will still be capable of dx.
If I worked all dx on 80, I'd rather have the vertical, but being I
don't,
I prefer the dipole.
Each band is different, and it always depends on what path/distance
etc, I want to work as far as the preferred antenna.
In general, I'd prefer the vertical on 160m.
Dipole for 80 and 40, and usually 20.
I've tried both a 1/4 GP and a dipole on 20m for average use,
and found I prefer the dipole. Probably ditto for 17,15.
But on 10m, I prefer a 1/2, 5/8 vertical if I can't have a beam.
On 10m, you see quite a bit of local chatter, and most tend
to run vertical if they want a decent ground/space wave.
It also gives them a good dx signal. If you run a dipole on 10m,
your long haul will be good, but local operation fairly poor.
There really is no best type antenna except to suit the job at
hand. If I'm on 40m in the day, give me me a good dipole,
loop, etc . But 40m at night 800-1000 miles to the coasts?
I'd rather be sitting in my truck running the mobile. No joke.
It will do a better job vs my appx 40 ft tall dipole. That
was tested over and over again. No fluke of the band cdx.
On 40 at night, which is best will nearly always be distance
determined. Look at the lowly efficiency of the mobile vs
the dipole. At night, it doesn't really mean squat. What matters
is that you have radiation at the angle you need to make that
hop. My mobile spits more rf at the desired angle than my
40 ft high dipole does at those semi low angles despite being
half crippled as far as efficiency vs a full size antenna.
So polarization is nothing to ignore if you want the best
bang for the buck. I bet my mobile ant sitting sideways would
be pretty lame in that case. Or say take two like mobile antennas
and make a short dipole. It would stink up the place on those
long hauls vs the normal vertical mobile antenna. But it might be
slightly better in the day working 200 miles away.
The best is to have both. :) And use a switch to be able to
quickly compare. You will see some interesting things as
far as band cdx, signal fluctuations, etc over time.
It really boils down to using experience working the various bands,

at the various times of day, season, to know which will likely
be the best at a given time. It's 1.49 in the AM here right now.
If I had to get on 40m right now, give me the vertical any day.
That would change in a few hours though when I started losing the
long haul stuff and had it replaced by the various old farts and
rednecks I work on a more local scale. :/ I'd then be on the dipole.
MK

Source record: 64728

Hello Dan,

concerning the 'Edit' option being available, this depends on the allowable actions for the object-type selected to edit and/or add. The number of items under the 'Edit' option also depends on the object-type selected.
You can also click a wire, EX or LD and then use the right mouse-button to enter the edit-menu.

About the Control-M, probably I forgot what to use it for. Could you give me a hint what you would like to do with this.

Arie.

==========
Yes, the loading coil is located next to the feedpoint. I forgot to
mention it in the program notes.

The antenna used with a counterpoise will very likely be a simple
vertical or an inverted-L

When the counterpoise is not near the ground the radiation pattern of
the whole system, antenna plus counterpoise plus feedline, will be
somthing like that of a bent, off-centre-fed dipole, which extends
between the top of the vertical antenna and the end of the
counterpoise, and slopes at an angle relative to the vertical.

It will be non-descript and have no interesting properties, not worth
the time and trouble of modelling with Eznec.

When the counterpoise is lying on the ground the radiation pattern
will be similar to that of the antenna alone. But it cannot be
modelled with Eznec.

Counterpoises are useful because they allow end-fed antennas to work
moderately well, at one frequency, when a good ground connection is
not available. With an antenna wire they behave as an off-cenre-fed
bent dipole with one end near the ground.

Reg.

Hi Bryan

I'd try and model this for you but the s/w I use is broken at the moment.

You can calculate path loss over an LOS path fairly easily. If you start with the RF output in dBm, add antenna gains, subtract the path and cable losses you'll get a close result. This can then be applied against the receiver sensitivity (I use to use -87dBm for 802.11 links) If you want to model in the existence of a reflector or (say) back to back yagi you do it is two paths using the received power at the reflecting device as the source power for the next minus about 3dB. The results tend to be less than encouraging in most places but it depends on the application. One study I did (for example) was to get a 410MHz signal into a railway cutting on the edge of a mountain. (ie no source of reflection from the other side) The 25W TX was about 2km away and we modeled two back to back 13dBi antennas. With -82dBm as the lowest specd RX signal we only got about 300m range from the reflecting array.

Freds suggestion of using a billboard is however a good one and simple to experiment with. I also agree that the powerline wont be much help.

Pls tell us how it works out!

Cheers Bob VK2YQA

buy a fishing rod and hang up a inverted v.
If you feed it with 300Ohm line or even loudspeaker cable you don't need a
balun up the rod.
Match it with a 1:1 balun or a simple Zmatch (emtech).
It works simple and very good...

1122. ATAS-120/Screwdriver question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-02 17:55:08 UTC
From: "Joe S." <anon@mous.com>
Message-ID: <19udnaOc-K772n_eRVn-hA@comcast.com>
Source record: 64733

I recently installed a Yaesu FT-857D and ATAS-120 on my truck to replace the truck and rig that were destroyed in Hurricane Katrina.

I have one nagging problem with this new installation I did not have with the previous installation. With the new installation, I went through all the setup steps with the rig and antenna. With my old installation, when I changed bands and hit the PTT button, the antenna automatically tuned itself -- the display would say WAIT and the meter would display high SWR -- I could hear the antenna tuning, the SWR would drop, and the rig would be ready to use on the new frequency.

Now, the antenna does not tune automatically upon changing bands or upon wide freq changes within the same band. If I set the rig on memory function "k" and hit the TUNE button, the antenna tunes, the display says WAIT, SWR shows high, and the antenna tunes then the rig beeps and I'm ready to go.

Have I missed something in the setup to make this thing tune automatically upon band change? I have searched and searched the manaul and don't find anything that I did not do when I installed the rig.

Now, I leave the memory set on "k" and just hit the TUNE button when I change bands, but, being basically lazy, I want the rig to do all the work for me.

Second problem: This morning I worked 40, 20, and 15 meters. Turned the rig off, went inside, came back out, tried to change bands and the antenna would not tune. I went back to the antenna and jiggled the upper trombone portion -- the part the moves up and down when it tunes -- went back and it worked fine. Is there some way to lube the ATAS-120, or, was this just a glitch that will happen from time to time?

Thanks.

1123. Mobile antenna mount

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-02 18:00:43 UTC
From: "Joe S." <anon@mous.com>
Message-ID: <a9idnVevv8Eo1X_enZ2dnUVZ_sydnZ2d@comcast.com>
Source record: 64734

I recently installed a Yaesu FT-857D on my truck. I installed two antennas -- ATAS-120 for HF and 6, dual-bander for VHF/UHF.

I used the stake hole mount from GeoTools -- this is one slick antenna mount. If you're looking for a no-holes mount and don't like the trunk-lip mounts, check it out. I mounted my antennas in the rear stake holes. I use my truck as a work truck and, so far, the antennas have not interfered with hauling. If they do, it's a simple matter of unscrewing the antenna, screwing a protective cap onto the mount threads, and hauling away.

No, I am not getting a commission from GeoTools -- it worked for me and may work for someone else.

Well the downside is that I dont think I can pull off the reflector senerio or complete line of site going over the tree's. At the end of this powerline is someone else's lot so I can't place anything on or around that. I only have permission to put the unit in the building located behind someone's house. Ideally I would rather not have any external antenna's on the building if at all possible to make the intrusion on property as light as possible. Thats what brought me to my question. The building is just an old cheap yard shed more than anything. It has power and 2 windows on the back side facing the back of the lot. I hope to be able to place the wireless unit close to the window which should help push the signal. If the building was another 25-30 foot more to the right I might would have LOS to it but that is also when you cross over onto someone elses land which is not an option. As for seeing the signal I am almost completely positive the grid antenna would be able to intersect the wireless signal at the end of the powerline but I am unsure if that is enough to get the signal back?

To see a very rough layout of what I am refering to see this
http://home.triad.rr.com/tempdir/images/layout.jpg

In support of Cecil's project of listening on a horizontal, while transmitting on a vertical, I have tried an experiment this evening, and will report on the results so far

While listening to an OK3 station this evening on 3.7995, I tuned two separate radios to the frequency.

Radio 1 is an IC-745 with a Butternut HF6V. 20 some radials. decent soil. Seems to work "well".

Radio 2 is an IC-761 on an OCF dipole. Also works pretty "well"

Noise level on the Vertical setup is S-8.

Noise level on the horizontal is S-4.

Mr. OK3 is at almost S-9 on the Vertical, and around S-7 to nearly S-8 on the horizontal.

Of course these two rigs have not been calibrated against each other. So I can only say that at least from his location, he is putting a bit stronger a signal (as far as the antenna is concerned) into the Middle of Pennsylvania .

But here is the interesting thing. On the horizontal antenna, the listening is a whole heckava lot more pleasant. Another item of interest is that in a recent exchange between the OK3 and a VE3, I could catch the Canadian station on my horizontal setup, while he was in the noise on the vertical.

This is an early stage of the experiment, but
I believe that there is a lot to say with the lower noise on the horizontal antenna station.

"On the other hand, a simple vertical does reasonably well when working just across country because of the short propagation path, almost straight up and down again, even via the groundwave for a very short distance."

True, but the thread is: "Verticals versus Horizontal Dipoles". Reg`s choice, I think.

Verticals have a null toward the zenith which tends to impair their "straight up and down again" performance. The horizontal dipole`s nulls are at its tips, too, but are pointed elsewhere, not at the zenith. This mey actually avoid some noise and interference beyond that originating in the directions of straight up or down again. As much noise is vertically polarized, it may be rejected by ctoss-polarization.

The horizontal dipole performs pretty well in the directions near the zenith when it is elevated at less than 1/2-wavelength in height, and for frequencies below the maximum usable frequency at near vertical incidence. At 1/2-wavelength elevation, the horizondal dipole develops a null toward the zenith, too.

Propagation of H-F signals via the groundwave is for a very short distance indeed. Frequency has a pronounced effect upon sffective earth conductivity. Conductivity falls fast with increasing frequency due to skin effect. . The earth layer penetrated by the wave thins as frequency increases, making it less conductive and increases loss. For example, over soil of 10 mmhos/m, a fairly common value, a transmitter would have to ptoduce 1,000 times more power at 5 MHz to produce the same signal at 10 miles as would a 0.5 MHz transmitter.

The earth`s attenuation of low-angle radiation from a 1/4-wave vertical antenna has a significant effect on the vertical radiation pattern. ee Fig. 54-1 on page 465 of B. Whitfield Griffith`s "Radio-Electronic Transmission Fundamentals". This figure shows field intensity curves versus vertical angle from a 1/4-wave vertical antenna radiating 1 kilowatt over earth of average conductivity. Anything below about 5-degrees is gone, eaten by the earth`s losses.

I conclude that for high frequencies, unless you have good or very good conductivity soil, horizontal polarization will likely serve you better than vertical polarization.

If you are at sea or immediately on the sea shore, you likely may do better with vertical polarization.

There are so many variables that it would likely be best to have antennas of both polarizations available, and to use the antenna which gave the best signal in the particular instance.

Best regards, Richard Harrison, KB5WZI

> Frank GM0CSZ / KN6WH
==========

Frank, the effectiveness of a counterpoise depends on its input resistance. The lower this resistance better it is. It is the 'ground' connection for the antenna. (And the transmitter).

But there's no point in making it longer than 1/4-wave. This increases coupling with the ground, increases loss resistance and also undesirably increases radiation resistance. The counterpoise then behaves more like a very low antenna.

When it is 1/2-wavelength long it has a very high input resistance and is entirely non-effective. It may just as well not be there.

At some lengths the loading coil would have to be replaced with a loading capacitor.

Remember, the antenna wire plus counterpoise is behaving as an off-centre fed, bent, dipole with the lower section being very near to the lossy ground. (Whatever the ground is). We don't want the lower section to be TOO long. The current into the counterpoise is the same current as is entering the antenna. If there is an antenna tuning unit it will tune up the counterpoise simultaneously with the antenna. They behave together as one thing!

So there is no point in having a separate tuner just for the counterpoise. Maximum current flows into the counterpoise at the same time as it flows into the antenna proper.

The purpose of the loading coil in the counterpoise is to provide a low impedance connection to the braid of the coaxial feedline. If there is no feedline then it provides an artificial 'ground' for the transmitter plus tuner.

And all the foregoing arises because it is difficult or impossible for the station owner to provide a set of buried ground radials.

>This is an early stage of the experiment, but
>I believe that there is a lot to say with the lower noise on the
>horizontal antenna station

Probably has a lot to do with the particular sites
though. It's quite possible to be near a noise source
that is mainly vertical polarized. In a case like that, it's
possible it could be a problem. But I never saw the difference
in noise levels you are seeing. At the worst, I might see
appx 2 S units, but sometimes it might only be one, or
even other times , nearly no difference at all. Most of
the noise I would see at this location is power line noise.
It seems to effect both horizontal and vertical nearly equally. :(
Probably cuz much is radiated by horizontal power lines.
I've never tested it, but I think if you are in a noiseless location,
the difference would be fairly small as far as meter readings
just measuring the average atmospheric noise. The reason I
say this is because sometimes I would see little difference in
noise between the two. But other times I might see more.
But you could see small differences just from the increase in
strength of dx signals. IE: if you had T-storms 1500 miles away,
it's quite likely the vertical will receive them stronger than the
horizontal due to the normal operation of the antennas.
Anyway, I don't totally consider what you see as the norm. "4 s units"
You probably have a local vertical noise source nearby. If it's power
line, etc, you might be able to track it down and get it fixed. :)
I'd be curious to see if you see the same 4 S unit noise difference
over a period of time. Like I say, mine would vary. But noise
never was much of a concern on mine. Never gave it much thought
at all. Kinda weird too being I'm in a big city, in a residential area.

Being mine was elevated at 36 ft at the base, I also had a pretty
good line of sight to any potential noise sources.
The tip of the radiator was at about 68 ft. As far as the VE being
better on the wire, that's probably fairly normal, being he wasn't dx.

Also, as a final note, while your butternut with 20 radials is ok, it
still
isn't quite up to the performance I saw with mine at 36 ft, using a
full size antenna. So I saw a larger signal increase on the dx than you

I bet. Mine was appx equal to a full length monopole with 60 radials,
if ground mounted. I'd have to look, but my ground may be a bit better
too. I'm right on the edge of being in a "30" zone. Of course, raising
efficiency raises s/n equally, but I noticed that I never saw the same

performance I had with the ground plane, when I ran the same full size vertical on the ground with 32 radials. That antenna was about equal to my dipoles at 1500 miles. Maybe a small bit better, but not any 2 S units worth like the GP was. So regardless of some saying the number of radials is not too important, it must be, if you want the best
performance. Sure made a difference here...
Either that, or elevating it above the surroundings makes the difference.
Myself, I think it's about 75% the first, and 25% the second... Elevating
the antenna for sure increased my local ground wave. I could work 50 miles away ground wave easy. I'd have cases in the daytime where I'd lose locals due to the band stretching out. But I could still nail them at
S 9 using the GP, where the dipole would be hard to read backscatter. Of course, if the band was open short, I'd be 10-20-30 over 9 on the dipole
to the same location.
Anyway, I guess you gotta use what works, but I don't think it's totally
normal to see a huge difference in noise between vertical and horizontal
unless something local is the culprit.

1129. Pulley Arrangement For Horiz. Antenna ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-03 12:46:17 UTC
From: Robert11 <rgsros@notme.com>

Hi,

Pretty sure I'll probably be able to come up with something that will more or less work, but was wondering if any of you folks have a real clever solution for this:

Will be stringing a horiz wire listening only antenna between two trees out back.
Trees have a fair amount of movement, particularly in the winter.

So, I thought I'd fasten one end securely, and then use the pulley arrangement, with a hanging weight, like you see in all the pix for this sort of thing.

But, we get a lot of ice and freezing rain, and I doubt that the pulley would really function well, if at all in the winter.
But, perhaps ?

Think a large metal ring, with a Dacron rope goint thru (one end to the wire end) would be better ?
Coat Dacron with Silicone Spray ?

Or,... ?

Bob

This certainly is not true for frequencies below about 2 MHz. If it was true, MW broadcast stations would have no groundwave coverage -- which of course is the only useful coverage they _do_ have in the daytime.

A monopole vertical radiator of any length up to 5/8-wave, when used with a ground system of ~120 buried radials each ~1/2-wave long, radiates its peak field very nearly in the horizontal plane regardless of the conductivity of the ground in which the radials are buried. This gain is within a few percent of the theoretical peak gain for these radiators when working against an infinite, perfectly conducting ground plane, as was demonstrated by the field tests of Brown, Lewis & Epstein in 1937. This principle has been accepted and used by the FCC and other regulating agencies, and has been field-proven in thousands of installations going back many decades.

Once "launched," the groundwave signal is affected by ground conductivity along the propagation path, earth curvature, obstructions etc. Groundwave path loss increases with increasing frequency, and above some frequency in the low HF range, the groundwave is unable to serve a practical purpose. But that doesn't necessarily mean that the transmit antenna did not generate the groundwave in the first place, ie, that it radiated zero field in the horizontal plane and at very low elevation angles.

One alternative is to use whatever pulley arrangement you can, and to add a spring between the rope and end of the antenna (insulator would probably be worth having too). How big of a spring? Beats me, how big/heavy is your antenna?

Source record: 64743

My geometric argument that beyond distances of several hundred, perhaps 500 miles, the vertical puts down a stronger signal and receives stronger signals than the horizontal dipole cannot be disputed.

If you can't be heard at 1000 miles or more using a dipole, you are more likely to be heard using a vertical regardless of what antenna the other fellow is using to receive. At great distances you are much more likely to be heard using a vertical at the same average height above its surroundings.

Signal to noise ratio does matter of course.

Local noise level is much greater than received from distance sources for obvious reasons. Local noise is vertically polarised. It comes in via groundwave.

Noise from a distance is randomly polarised. It comes in via the ionosphere. So in towns and cities, with buildings wiring, overhead power and phone lines, where most of us live, the vertical collects more local noise. In the wide open countryside both types of antenna tend to perform equally well on randomly polarised, distant noise levels.

With distant noise and interference and distant signals, both types of antenna result in the same signal to noise ratio in the receiver. But the vertical antenna receives the stronger signal plus noise. If the internal receiver noise is greater than the received signal plus noise then the vertical antenna will win the contest.

However, there is another effect which sometimes gives the dipole the advantage. It is multi-hop propagation.

The angle of elevation of the radio path increases with the number of hops involved. The number of hops depends on the sun-angle and day or nighttime. Across the States or across the Pacific, for example, the propagation loss can be much less with 2 or 3 hops than it is with one or two hops. Waves sometimes bounce between the F2 and E layers. The increase in elevation angle favours the horizontal dipole. And how many amateurs know the number of hops involved at any point in time?

But what eventually favours the vertical over the dipole is their respective service areas. The service area covered by the vertical is many times, far greater than the dipole and so is the world wide distribution of radio amateurs and short-wave listeners.

We have now returned to the simplistic but precise Geometry of the
ancient Egyptians and Greeks. ;o)

Bob,
Pulley's and jugs of anti-freeze have worked well for me through 5 winters
here in NH.
No apparent problems with "boat pulleys" seizing up. I would worry more
about friction on the
rope!. My 220 foot antenna of #10 copperweld with W7FG ladderline requires 5
gallon jugs of
anti-freeze and is supported with the double braided Dacron in about a 300
foot span.

I use a marine pulley. It is rated at 700 LBS, its housing is made of stainless steel and the wheel is nylon. I have a 200+ foot span between some very high fir trees. These suckers really whip around when those Pacific winter storms hit. Mine system has been up for over ten years with out any mishaps.

To the extent that this is true, it is not just a function of the intrinsic radiation patterns of the (horizontally polarised) half-wave dipole and the vertical monopole, but also to the net gain toward the other end of the path including reflections of that intrinsic radiation from the physical environment around the antenna.

The performance of an antenna near the earth can depend as much on its installation conditions as its free space pattern.

Rich, all what you say is quite true - except that groundwave is
radiated at ALL frequencies from a vertical of 5/8-wave or shorter.

Useful propagation occurs at 30 MHz and below. But loss in the ground
and loss due to obstructions above 1/4-wave in height is high. Solid
ragchews across town and small city are quite possible on the 10m
band.

For predicting groundwave propagation from VLF to HF, download program

Hi Reg

Interesting stuff

I wonder however if you have any hard data on the merits of using one polarization over another in an electrically noisy environment. For years I have believed (but never seen proof) that on average horizontal is better for this.

Any comments? If it is horiz, why? Is it indeed the high radiation angle missing local noise makers or something else..?

Cheers Bob VK2YQA

In Colorado I had a 150' balanced fed dipole hung between a blue spruce and an oak tree, the spruce end fastened and the oak end with a pulley held up with a garage door spring to the oak, a rope through the pulley to the ground and tied off to a screw eye in the trunk of the tree. I used nylon ropes, allowed the dipole to sag a couple feet and never had a problem with it. The garage door spring was about 4 feet long relaxed and I could stretch it a foot or so just pulling on it, it was stretched maybe two feet with the antenna up. The pulley was handy because the feed line broke off and I was able to lower the feed point to the ground and make repairs. The antenna would bounce around on windy days, stayed up with about an inch coating of snow and ice and got me a QSL card from a Clipperton Island expedition.

Hi Bryan

Am a little confused. Probably from working nights and not getting
enough sleep!

From your diagram you are trying to get a signal between the site that
has the 24dB gridpack and the "Outside building". You have done some
tests from the road and it seems to work.

I'd expect you biggest prohblem is the pine forest. They are excellent
for attenuating microwave signals! My gut feel is that you'll need a
gain antenna at the "outside building" as well as the existing one. This
very much depends on the pine tree density that I dont have any actual
attenuation figures on. I actually modelled a 2.4GHz link to my mother
in laws place about half a mile away through trees and with gridpacks at
each end. I had about 50dB of margin but was still worried about 100-200
yards of pine trees. If nothing else you'll get multipath interference
and may need to play with polarization.

If all else fails try bouncing the signal off the house. You might be
surprised!

Sorry I cant be more helpful. Pine needles and tree trunks I dont have
any figures on!

Cheers Bob

You are right in that I am attempting to pass the signal from the building to the 24db antenna down the powerline NLOS. Distance wise I have passed the signal even further than I need NLOS but it was a strait shot NLOS not off to the right like I am going to attempt. I will be able to actually try this tomorrow and may post my results.

==========

Local noise is stronger in terms of milli-volts per meter than distant noise for obvious reasons. It is nearer and man-made.

Local noise is vertically polarised and comes in via the groundwave and at low elevation angles.

Therfore, a vertical antenna which is most sensitive to vertical polarisation and to signals and noise coming from low angles produces greater low-angle signals and low-angle noise in the receiver.

Whereas, distant noise comes in from high angles via the ionosphere and is randomly polarised. It is weaker than local noise. It depends on lattitude, the sun, day or night and season of the year.

Therefore, a horizontal dipole which is most sensitive to signals and noise coming in from the higher angles produces greater high-angle signals and high-angle noise in the receiver.

Now carry on from there. Compare a dipole receiving a low-angle signal with high-angle noise coming in from all directions, with a vertical antenna receiving a high-angle signal with low-angle noise coming in from all directions.

Reg.

> angles around 45 degrees performance is about the same for both types.

No, at 45 degrees the PATTERN is about the same (assuming that the
horizontal antenna is at least .25 wavelength high). But the actual GAIN
over an isotropic source is equivalent down at around 25 degrees. That's
because the vertical is normally a monopole, the other half of which is
reflected in the ground, whereas the dipole is a dipole and its ground
reflection is therefore another dipole stacked with it. Ground losses
for the dipole occur at a lower incident angle and further from the
antenna and are thus lower.

Of course, you can have the best of both worlds by using a vertical
dipole, in which case your take-off angle will really be quite low.

The main reason why verticals tend to outperform dipoles on low-band DX
paths is that the dipoles and other horizontally polarized wires are
rarely very high. A lot of them are only about an eighth of a wavelength
up or even less. This increases ground losses at all angles and reduces
the efficiency of the antenna. And if you can get the current loop to
climb up the antenna (by top loading it), a vertical will compete very
strongly below about 30 degrees.

Reg wrote:
"If you can`t be heard at 1000 miles or more using a dipole, you are more likely to be heard using a vertical regardless of what the other fellow is using to receive."

That must not always be the case. Otherwise all the shortwave broadcast stations I`ve worked in, and seen for that matter, would not use horizontal antennas. They have no way of knowing what their audience will use for antennas, and it does not make much difference as following ionospheric reflection, all wave polarizations are available and may be received.

At the equator, a time zone is about 1000 miles wide. at the poles (a bad place for shortwave propagation) the width of a time zone is insignificant. All the stations I refer to are in the temperate zone and their targets are likely 1000 miles or so away, though some targets of some stations are only a few hundred miles away.

Antennas at these shortwave broadcast stations are a product of studying successful antennas and carefully designing new antennas anf testing their performance in and around their intended targets. They are proved to be effective.

Why would a vrtical antenna be better?

From Arnold B. Bailey`s giant antenna catalog in his "TV and Other Receiving Antennas", the free-space gain is the same for a ground plane as it is for a center-fed 1/2-wave dipole. An antenna`s proximity to the earth may change the balance between horizontal and vertical antennas.

Terman writes on page 886 of his 1955 edition:
"Consider an antenna that is far enough from ground so that the total power radiated by a given set of antenna currents is independent of the presence of the ground. Then a ground reflection that reinforces the main lobe will double the field strength of the main lobe, and so will increase directive gain of the antenna system by a factor of 4. This condition corresponds to an antenna height great enough to make the mutual impedance between the antenna and its image small (see page 894).With horizontally polarized systems this will be the case if the center of the antenna is at least one wavelength above ground; with vertically polarized systems it is true even at lower heights.

However. when the antenna is sufficiently close to the ground the effect of the ground reflection is to cause the directive gain to differ from 4. Thus , for a vertical doublet close to the ground, the directive gain is twice the free-space value, since the presence of the ground does not

alter the directional pattern and there is no energy radiated in the direction of the hemisphere occupied by the ground. In contrast, the directive gain of a horizontal antenna very close to the ground can be more than 4 as compared with the same antenna in free space, as discussed below in connection with Fig. 23-36."

Seems horizontal antenna users are not fools after all.

Best wishes, Richard Harrison, KB5WZI

1145. Another ATAS-120 -- FT-857D question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-03 21:27:59 UTC
From: "Joe S." <anon@mous.com>
Message-ID: <oPKdnWIIKaNUV37eRVn-og@comcast.com>
Source record: 64756

My FT-857 display is showing the word MTUNE. No mention of this in the manual. I went through the setup routine for the ATAS-120 and the antenna seems to be working fine -- it tunes when I change bands and I am making HF contacts on it.

Anyone know what this means?

Thanks.

"Memory Tune"

Google is your friend in this case. Get a searchable copy of the
Operating Manual and look for "mtune". Check the "Memory Operation"
section of the manual.

If you are stuck, I can send you the PDF I have.

Thanks -- I went to the Yaesu site and found a .pdf manual for the 857 and found MTUNE. Strange -- I can't figure out how I got into that mode. Well, anyway, I went back out to the truck a few minutes ago, screwed around with it and MTUNE has disappeared from the display and the rig and antenna are working normally.

Life was so much more simple with a pi-network and dozen or so knobs to turn while watching the meters :-)

I suspect so also. Maybe some day I'll test that out. The Butternut can
be removed and remounted pretty easily. There is a low noise area where
we have FD. Maybe I'll haul the vertical out there some weekend.

> to the same location.

One thing that I am seeing is that different signals originating from
different locations are coming in at different strengths on the two
radios with the different antennas. This is fascinating. I've been
listening tonight to a VE, a Pennsylvania ham, and another from South
America.

I suppose that a lot of hams may be used to this, but I find it very
cool - I suppose that the different signals coming in at different
angles are "caught" by the different antennas differently. I gotta get
these two meters calibrated against each other.

> Anyway, I guess you gotta use what works, but I don't think it's

Could be a local problem - that one is harder for me to troubleshoot. I would say that the noise is probably not power line source. It is a sort of crashing noise. Almost like lightning noise, but occurring more often, and less powerful. Could be southern hemisphere lightning storms?

Mike, you will be aware that a lot of commercial HF amateur
transceivers have two HF antenna sockets which can be selected from
the front panel. I have always wondered why they do not support a mode
of tx on Ant-1, rx on Ant-2 to conveniently support the very
configuration you are using.

>... [snipping pulley and weight vs. spring discussion...]

Instead of pulleys, I use a fairly-large (they come in several sizes)
screw-in glass insulators like you might use when running a power line;
they are easy to install, plenty strong enough, there's no danger of
the rope slipping off the pulley wheel, and they are smooth enough that
I've never had a rope break because of chafing.

And instead of weights, I use one/two/three/... (as many as I think the
length and weight of wire needs) screen-door-type springs; they're cheap
and seem to last forever. They can be overstretched, but they're cheap....

If you do use a weight, be sure to tie it up (loosely) in such a way that
if the antenna breaks, the weight won't clobber someone who just happens
to be standing below it!

For a 130 foot dipole stretched between 3 trees, I use inexpensive
screen door springs from the hardware store at each end. The springs
get rusty, but still work and my antenna has yet to break.

If you don't have a signal generator with variable output, connect the two feedlines through a DPDT switch so it swaps the antenna to each receiver when you switch it back and forth. Write down the meter reading on each receiver for the same signal from the same antenna. It probably won't take long to accumulate a decent cross reference.

Of course, you still won't have a clue as to how many dB each meter unit represents. That'll take an investment of a few dollars and an evening to make a step attenuator.

Ya beat me to it. I agree. I'm on my way to putting up some HF - UHF antennas and that's exactly the approach I'll use. Take a couple feet of coax and install a connector on one end. Then drill a hole thru the wall which is just slightly bigger in diameter than the coax. Fish the coax through the hole with the already-installed connector on the outside of the wall then install the inside connector on the inside end of the jumper when I'm inside and out of the weather.

In my case I'll be using 8X coax for my HF antennas and a 9/32"- 5/16" inch drill which makes a much smaller hole to drill and patch and "make disappear" years from now when I go SK or move. Versus the 5/8" hole required to install a UHF feedthru. There are also some cost saving advantages to not using feedthrus. I drill the holes slightly inclined down toward the outside to keep water from migrating along the coax toward the inside.

A greatly overlooked item of test equipment.

I recall advising a ham to buy a HP355 step attenuator so that he could quantify the level of interference from nearby power leaks and build a prime facie case for non compliance with emission standards.

Although he had just winged at length about his $20,000 plus investment in a tower and VHF/UHF antennas, more on radios, etc... he baulked at spending a $100 on something as unexciting as a step attenuator. This was an opportunity to learn a little more about predicting path loss than a $100 burden.

As part of my FSM project for measuring BPL emissions, I went searching the net for kits for RF step attenuators, and all that I found were kits that had gone obsolete, no longer available. Today it should be a piece of cake to do a low cost kit with miniature switches, precision surface mount resistors etc... but we as a community are apparently not sufficiently interested in quantifying things these days.

1161. More ATAS-120 problems

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-04 22:10:50 UTC
From: "Joe S." <anon@mous.com>
Message-ID: <5JGdneVCIKrJu3jenZ2dnUVZ_sCdnZ2d@comcast.com>
Source record: 64771

I installed a FT-857D and ATAS-120 on my truck. Everything worked fine after the installation but now something has happened.

The rig does not recognize the antenna. I have gone through the antenna initialization steps several times. I even reset the rig to default positions and set up the antenna again.

Normally, when the ATAS is connected and tuned, the display will show ATAS. If the antenna is not tuned, the display shows lower case atas until it is tuned then it switches to ATAS.

Normally when you change frequenct and hit the TUNE button, the display says WAIT and the antenna tunes itself. Now, when I hit the TUNE button, the rig beeps once as though it is starting to tune the rig then it immediatly beeps twice -- neither ATAS nor WAIT appears in the display.

I do not get an ATAS or atas on the display. When I press the TUNE button, instead of tuning the antenna, the rig beeps, then beeps twice, and that's it.

I have double-checked the coax and there are no problems with it. Checked and double-checked all wiring and installations.

Anyone have any suggestions?

Thanks.

A step attenuator which is completely adequate for HF and can easily resolve 1 dB can be made from a few cheap slide switches, some PC board material, and a handful of ordinary 5% quarter watt resistors. Detailed instructions can be found in numerous sources, including the Web -- a Google search brought a large number of hits, the first of which was http://www.arrl.org/tis/info/pdf/9506033.pdf. But I'm afraid that this level of homebrewing is beyond the interest if not the ability of the majority of today's amateurs.

Tnxs for that Reg

What is the generally accepted "number" in either S points or dB of employing horizontal instead of vertical for noise reasons? Obviously it would vary greatly but any idea you have would be helpful. I would also like to get an idea how "critical" it is to make sure ones antenna truly is horizontal (eg not an inverted V or quad loop) if noise is the greatest concern.

One would assume you also get a similar affect of "less horizontal noise" from the actual noise source for the same reason. eg power lines radiate well upwards but not so well in groundwave.

Bob,

First of all we must entirely disregard the opinions of individuals who may be located in high or low noise districts, areas or regions. I myself live in an industrial, densely populated, area near to a factory with a dozen electrical arc welding machines. Others live out in the wilderness, isolated from modern, electrical noise generating civilisation.

There exist statistics of AVERAGE field strength noise levels experienced in cities, small towns and in the open countryside. I have forgotten where to find such statistics but Google may help.

The statistics depend very much on frequency. They vary greatly between ELF and HF. Noise levels decrease by crudely 10 dB or 20 dB per octave or decade increase in frequency.

Furthermore, at ELF and VLF, noise propagates to far greater distances than at HF. There are always continuous world-wide electrical storms somewhere on the Earth's surface.

At 10 KHz noise levels may be several hundred milli-volts per meter. At 7 MHz they may be microvolts per meter. At 30 MHz they are of the order of the internal receiver noise.

The noise level indicated by your S-meter is a function of the size of the antenna relative to wavelength and antenna efficiency. It can be crudely calibrated in terms of micro-volts per metre using a little arithmetic. Learn how to estimate.

In my own experience (which as I say should be disregarded) the difference in noise level between a horizontal dipole and a vertical is about one or two S-points on the 160 metre band. (Or a difference of 6 or 12 dB.)

On the other hand, distant stations come in stronger using a 150-feet, vertical (inverted-L) than they do on a dipole. Not that I have ever used the two types of antenna simultaneously. It's just my opinion. So I prefer the inverted-L. In general, the signal to noise ratio is

better and there is less fading. One hop instead of two, via the
F2-layer, at night, using a dipole?

Quick reply and first thoughts: Is it possibly a marine/boat antenna
with the four channels you listed??

1176. Anti-oxidant grease question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-05 14:02:04 UTC
From: "Joe S." <anon@mous.com>
Message-ID: <k6GdnXJ347bbmHveRVn-jw@comcast.com>
Source record: 64637

How do I apply anti-oxidant grease to the junction of two metals? Do I put a dab of grease on each mating surface then clamp the metals together, or, clamp the metals together and smear grease on the outside?

I have a Yaesu FT-857D and an ATAS-120 installed in my truck -- I have had a problem with the ATAS-120 -- my FT-857D would not recognize the antenna. After checking every possible problem, I made a discovery.

Using my ohmmeter, I found there was continuity between the antenna mount and the body and frame of the truck, but, there was no continuity between the antenna connector and the antenna mount. The connecter is a VHF Type M mount; the threaded portion of the connector passes through a hole in the antenna mount and is tightened to the mount with a big nut. There was no connection between the connector and the antenna mount, thus, there was no connection between the outer shell of the antenna connector and the truck frame and body.

I removed the big nut that holds the antenna connector and used emery paper to sand the surface of the nut that contacts the mount, and, I sanded the part of the mount that contacts the nut. When I re-installed the antenna connector, the antenna works perfectly. The problem was a bad ground between the antenna connector and the antenna mount because of oxidation on the two mating surfaces.

I have found a source of anti-oxidant grease that's used on electrical connections and I will put this stuff on the connector-mount junction to prevent further oxidation. Here's the question: Do I loosen the nut and put grease between the nut and the antenna mount -- similar to putting thermal grease between a heat sink and the surface of a transistor -- or, do I tighten the nut and smear grease on the outside, not on the mating surfaces? I suspect I should put the grease on the mating surfaces between the nut and the mount -- loosen the nut, smear on grease, tighten the nut.

Thanks.

www.thewireman.com has bulkhead double-female feedthroughs, some for
regular UHF connectors, and, yes, some for N connectors. You could
call them to get the various lengths they have in stock.

Hi Dan

Yes I have tried and failed so far encountering a series of problems centered around the bat file. Its been a while though so pls take the following with memory fade in mind!

- The actual necd2.exe file baulks under wine with some kind of malloc problem. I have however succesfully run it under DOSEMU, the DOS emulator. The original problem I had under wine was also wine version specific but I cant remember the details.

- The BAT file supplied by Arie has some characters/syntax that are illegal under wine/DOSEMU. From memory these were tabs somewhere. Replacing them with spaces fixed things. I dont know if Arie addressed this in later versions or not.

- I had the system running at one stage by using the GUI and getting an error doing the calculation. I then ran it manually under DOSEMU and loaded the output file back into the GUI. Clunky but usable. My next effort was going to be to modify the bat file as supplied with a pause statement (and no calc) that gave me time to launch my own script under DOSEMU. I was also looking into some way to launch a Linux script from a bat file but never delved into that too far.

Hope this helps.. If I get excited over fixing this I may do some more experimentation

Cheers Bob W5/VK2YQA

The anytioxidant has to be in intimate contact with the metal surfaces
before they are clamped together. Here is a site that tells how to
use one version, Penetrox-A. The details are about 1/4 of the way down:
http://www.inspect-ny.com/aluminum/alreduce.htm#1A

John:

THANK YOU!!! Exactly what I needed -- I don't know how you found that -- I spent an hour searching with Google for various combinations of anti-oxidant, antioxidant, applying, application, etc., etc.

I'll pick up a tube/can/jug/whatever of Penetrox tomorrow at my local electrical supply house, disassemble both antenna mounts and connectors, "abrade" them thoroughly, and slap the Penetrox onto every metal-to-metal junction.

Thanks again.

73,
Joe

Obviously one must fill the extra space with something just to keep bugs, snakes, and mice from crawling in, but foaming seems sorta final in that, when one wants to add another coax, the foam will need to be dug out.

I've always just stuffed fiberglas insulation around the coax, but here's a QUESTION: Would using steel wool (which mice won't chew) affect currents in and/or on the coax?

It took a few tries, including adding the words [aluminum copper
electrical] to reduce the diet pill adds.

For aluminum, (which oxidizes almost instantly in contact with air)
they recommend coating the surface and then doing the final abrading,
so the fresh surface has no contact, at all, with air, before the
joint is assembled. It sounds a little like trying to make a dry
joint under water.

Naw, it won't have any noticeable effect on the coax. Sometime ago
some proposed packing steel wool around coax as a common mode choke,
however, Walter Maxwell did some measurements and found that was just
about worthless for choking.

Foam is not a good idea. It can become very difficult to remove.

Best is to use cooper wool. It will not rust nor flake and beasties do
not eat it. The stuff has become hard to find, however.

FOAM?? No!

Dick, get a tube of colored caulking compound. I use BROWN for a brown house [of course]. It makes a weather and insect proof seal and is easily removed if needed [simply pull the coax and both the coax and caulking come right out].

Dave

Thanks for pointing out that procedure. I noticed that in the instructions
you sent and I figured the rapid oxidation of aluminum was the reason.

well none of the above stops the Lightning getting into shack and racing
around zapping all and sundry ?
i got a Border Collie here that could get coax into a shack, stop getting
gear zapped , well thats different
heres what I did,
get ur coax from INSIDE TO OUTER WALL,
Terminate it pl259's or whatever, make 2 pieces of ally box section that
will fit together, on the outer side, alighn SO-239's on both ally pieces,
one to collect the coax from INSIDE the shack, and another row to collect
the terminated coax from the antennas,, slide the ally box section together,
and connect centre of SO-239's to SO -239's with BANANA PLUG centres to
ensure a RF connection,
position a Bolt on one side of one ally section, and form a S shaped piece
of ally flat with a hole drilled into it, to take a thin piece of rope,
terminate all so-239s with appropiate coax's ?/ all done, STORM comes, pull
rope, S shape pivots against the bolt in the ally section and UNPLUGS all
antennas together, KEEPING all the nasties OUTSIDE, when storm has gone
plug it back in,
been using one for 15 yrs,

73
will gladly take some pics if anyone wants

C'Mon Mac,

Reggie has been doing this so many years, it's his trademark schtick.
To give Reggie credit where credit is due, can be found in a
remarkable body of work of programs. Unfortunately, this
accomplishment is seriously tipped out of balance when he scorns his
audience as software addicts.

Instead of teaching them Kelvin's principles by example, we get his
poor English stagings of Le Misanthrope de Moliere.

One of my favorite irascible English characters is Dr. Samuel Johnson,
but his ire is tempered with a faith in humanity:
"this boy rows us as well without learning, as if he could sing
the song of Orpheus to the Argonauts, who were the first sailors.'
He then called to the boy, 'What would you give, my lad, to know
about the Argonauts?' 'Sir (said the boy,) I would give what I
have.' Johnson was much pleased with his answer, and we gave him a
double fare. Dr. Johnson then turning to me, 'Sir, (said he) a
desire of knowledge is the natural feeling of mankind; and every
human being, whose mind is not debauched, will be willing to give
all that he has to get knowledge.' "

Ok, my first test failed so far. Example of what I am doing is here http://home.triad.rr.com/tempdir/images/layout.jpg. My next thing I am thinking about trying is to place some kind of somewhat small (no billboard) passive repeater at the end of the powerline attached to a utility pole where it meets the field. No power this far out and trenching is not an option. I can google and find hords of info about people using passive repeaters to bend the signal but I cannot find an actual passive repeater or how to build one. Also when dealing with this type of repeater would it force me to have directional antenna's at both ends where currently I have only the one directional parabolic grid at the top of the powerline and just a standard AP inside the building. Anyone think of anything else that may work. going over the forest is also not an option. I own the land where the grid antenna is located but I dont own the land where the building is located as I just have permission to place a AP at that site. I am trying to make the impact as minimal as possible at that site.

Bryan

Source record: 64659

Hi again Bryan

A passive repeater is very simple.

You simply take two antennas and join them with feeder, then point one antenna at one end of the link and the other at the other end of the link. You may need to separate them some so they dont interfere with each others capture pattern.

There will be a link budget that defines how much system gain (and thus antenna gain) you need. You could conceivably get away with using the standard AP antenna at that one end. As I said previously the software I use for this is broken and I am not in a position to redo it by hand just at the moment. There is a simple formula for determining path loss over a line of sight path. You just do that twice with the received strength at the repeater being the source power for the next link (minus about 3dB)

What are the distances from each site to the passive rptr location? If one does the calclulation then outoput power and receiver sensitivity is also needed.

Cheers Bob

==
Bob,

The angle of the 'horizontal' dipole relative to the horizontal, whether it is an inverted-V or not, makes negligible difference to the amount of noise it collects. It is non-critical in this respect.

The incoming, mainly distant noise comes in from all directions and angles and is randomly polarised. Except, that is, for locally generated noise, which is mainly a vertically polarised ground-wave and from low angles to which the horizontal dipole is quite insensitive.

Noise radiated from nearby elevated power lines is probably randomly polarised and is collected in similar proportions by both horizontal and vertical antennas. When a power line is half-mile or more away I would guess that the received noise reverts to vertically polarised groundwaves which at HF are rapidly attenuated. The horizontal waves are even more rapidly attenuated.

Noise can be studied only from its statistical probability distributions versus direction, angle, frequency, receiver bandwidth and time. The opinions and anecdotes of individuals matter only to the inviduals concerned and their locations on the Earth's surface.

Reg.

Maybe that is because the billboard reflector is close to 98% efficient,
while back-to-back antennas are only about 30% efficient.

The building location is maybe 500 feet away from where the repeater would be. The parabolic grid is maybe 3000-3500 feet away from the repeater location.

As for the output we will talk about the grid antenna first. It is currently at 28mw which is adjustable up to 250mw but I would be way over the limit with the 24db gain antenna (also the way I understand it which is a learning in process I should not need to increase the xmit power due to the focus of the directional type antenna). Plus since this will be out in the open in a sealed weather proof box I don't want heating problems or bird nuking etc.... Sadly I am unable to find out what the current MN-700 AP which is located in the building transmits at or what the gain of the stock antenna's is. I have purchased another AP similar to the one hooked to the grid antenna which by default would be transmitting at 28mw with 7db gain rubber duck antenna.

Passive antenna
"You simply take two antennas and join them with feeder". Help me out a bit here if possible. So I take two antenna's such as (http://sharperconcepts.zoovy.com/c=6buOjuTwyhk8OnXuIOz6ZqKK6/product/YSC-HG2409Y) and hook the pig tails together? Point one at the grid and one at the building right? Does the gain really matter? Do they need to both be directional?

"You may need to separate them some so they dont interfere with each others capture pattern."
I dont think this would be an issue as one would have to be on 1 side of the utility pole and one on the other. Do you think this would cause problems?

I'm helping the SDSU mechanical engineering students with their Rocket.
See: http://www-rohan.sdsu.edu/%7esharring/sdsurocket.html

I've asked for help on this group before, but the response went over my head.
I a reasonably skilled EE, with ZERO antenna design experience.

I would like to design an antenna that was conformal with the rocket main tube.
The rocket is about 8" in diameter and all metal.

I need two antennas....
I have two channels a 70cm ATV transmitter and a 900Mhz non-ham telemetry radio.

For the last attempt:

Telemetry: I put two 1/4 wave verticals on opposite sides of the rocket fed them with a minicircuits splitter.
This worked well as I got data from lift off to impact.

ATV Last attempt I just had a single 1/4 wave dipole sticking out one side of the rocket.
As the rocket rolled the signal faded in and out.

The last time I asked this question I got a response that I could not use because I did not understand it.

So I'm looking for someone to help that can do the detail design.

IE provide instructions build a tobe with this pattern on it, hook up coax here and trim this spot to adjust SWR.
I'm perfectly willing to get the fabrication done, but the design is beyond me.

I realize that I'm asking a lot, but any one that wants to help with the antenna can have a front row seat in the block house to watch it launch, and some cool video tape ;-)
(The launch will be at the MTA near Mojave, CA)

No, my response was factual, neumeric, and specific. It was not meant as a slam. Reflectors are less lossy than back-to-back antennas. If you are using microwaves, the size of the reflector may be practical.

The peflector in the path is most effective when placed near either end of the path. The reflector can also produce gain over that produced by the antennas at the path ends. It must be slightly concave to do so. Commercial reflectors often come equipped with an adjustment to suck in the center of the reflector for maximum gain once alignment of the dishes is accomplished. This isn`t speculation. I`ve designed the paths and performed the adjustments with my own hands.

It could be taken to the extreme. Rotated 90-degrees, the horizontal wire becomes a vertical wire. On its way to becoming a vertical wire, it is a sloping wire. The sloping wire responds with a vertical component in addition to its horizontal component. The sum of these components make up the wire`s total response.

To the best of my knowledge, Reg hit the nail squarely on the head in the rest of his posting about noise radiation and reception.

I guess that what you are saying is true.

But Truth and truth can be different things when I can take cold comfort that statistically the different antennas should "hear" the same, while my situation is otherwise. I get a lot of noise with it compared to my dipole. I doubt that I can do a lot about it. And while the antenna does pick up many desirable signals more strongly than the dipole, the dipole's relative quietness makes me believe that I may be able to discern weaker signals with more readability.

And whether my opinion is valid or not, I believe it is the truth of my situation, and many others.

Regardless of its noise properties, a quarter-wave and higher vertical
radiates more low-angle power than a half-wave horizontal dipole.
There's no argument. If you can't be heard then you can't work 'em.

Although a quarter-wave vertical radiates less power at high angles,
it can still be heard quite well because propagation distances covered
are relatively short.

The vertical is omni-directional. The dipole is not.

Skip-distances are the same for both vertical and horizontal. The
Ancient Greeks Geometry rules.

Therefore, the situation is biassed in favor of the vertical.

The dipole wins only when the local noise level is much higher than
atmospheric noise. If you live in or near a city then its your hard
luck. Most of us do!

You're very welcome.

The reason for my rather grumpy comment at the end is that I've recommended countless times for many years that people interested in evaluating antennas build a simple step attenuator -- an evening project. It allows you to make direct, quantitative comparisons between two antennas -- yours or someone else's, as well as calibrate your "S" meter. But to date, I've never gotten an iota of feedback that a single person has actually taken the trouble to build one. Rather, they continue to debate, ad nauseum and without any meaningful data, whether one antenna is better than the other, or at best quote differences in "S-units" read from their meters, without the foggiest idea how many dB it might represent or how different it is from someone else's meter (or from the same meter on a different band or a different part of the scale). The conclusion I've reached is that A) Hams would much rather argue than actually determine the facts, or B) The vast majority are unable to build a homebrew project consisting of slide switches, circuit board material, and resistors. I'm afraid both are probably true.

Maybe you'll be the first to actually build one. If so, please drop me an email and let me know -- it'll make my day!

==========

Roy, to cheer you up, many years back I made one in a diecast Eddystone box. The last decade was in 0.001 dB steps. It was intended only up to 5 MHz.

It was used to determine the attenuation/temperature coefficients of oceanic, submarine coaxial cables, 26 miles long, in tanks at the cable factory. Temperature was changed by dumping a ton of ice into the tank, obtained from Billingsgate, London, fish market. I think the fish market is still in Billingsgate but the attenuator has long since disappeared. Perhaps the knobs still exist somewhere. Very sad!

Example scenario:
There's a mountain between your house and the tv station and you cannot pick up a tv signal to watch.
SO - you buy 3 high-gain direction tv antennas at radio shack.
You go up to the top of the mountain and set one antenna to point to the tv station, and one of the other antennas to point toward your house.
The 2 antennas on the mountain feed to each other with 300-ohm ribbon cable-like the other antenna was the tv set. (one acts like a receiver, and the other like a transmitter.)
The third high-gain antenna is at your house - pointed to the antenna on top of the mountain. This antenna feeds to your tv.
So yes - you need directional antennas - three of them.
The antennas need to 'see' each other.
I heard of folks using rhombic antennas on the mtn (uhf and vhf) - good gain.

Hi. I'm looking for more creative ideas. I live in a typical suburban setting. I have a 100' oak tree out back with a clear base of 65' on to one side; 75' to the other. I've EZNEC'd a variety of antennas from center fed (ladder line) inverted vee resonant at about 2.4MHz. Moved to offset fed versions which works over more bands but still not quite a low enough swr to load with a palstar balanced tuner on 160. Moved on to a 'triangle' antenna made by adding a wire base to the inverted vee about 2-' off the ground. Now I've got enough length, but the swr is squirrely on all abnds because of the interaction of the short legs (I guess it's a short delta with only the driven element.). So, it appears I'll have to wait until the kids graduate and a move to the countryside is in order.
I know it won't work as well as a wavelength loop with a huge mesh metal fence counterpoise, but it would be nice to try and ragchew on 160m while the sunspot cycle is zilch. Any weird topologies come to mind? And still let me load up 80/40m?

unable to build a homebrew project consisting of slide switches,
circuit
board material, and resistors. I'm afraid both are probably true.
.....
.....
.....

In my case, I suppose I could build one. I am capable. But the honest
truth is I really don't care exactly how many DB's a certain antenna is
vs
another when testing on the air. Or how many DB's my S meter reads.
All I care about is which is better. A or B. The ionosphere will skew
any
measurements, so to me, not much point. Now, if I were testing
antennas against each other on a antenna testing range, I wouldn't be
without one.
As an example, if I were to measure the DB increase of a GP vs dipole
on 40m, the difference would increase as the path got farther and
farther.
I wouldn't really be measuring the antennas per say, I'd be measuring
the overall big picture including the propogation effects. So I don't
see
much need to put an exact number on it. As long as I can tell which is
better, I'm a happy camper. I'd use the attenuator when doing fine
comparions of antennas in a controlled envionement. IE: good for
measuring the gain of a homebrew 2m yagi, vs a dipole, etc in a
space wave envionment.
When quoting S meter readings, I never try to equate those with
any numerical gain.. It's just a relative method of seeing which one
is best.

From: Roy Lewallen <w7el@eznec.com>
Message-ID: <11ugs6fc94rabf4@corp.supernews.com>
Source record: 64580

I keep hearing about "passive repeaters", but haven't ever seen anything quantitative about how well they work. I had some measurements done years ago which showed that a cell phone "passive repeater" in a sedan doesn't do anything significant, quite obviously because the windows are such large apertures at that frequency.

But here are some numbers to work with. Corrections are welcome.

Assuming perfect efficiency, the maximum effective aperture of an antenna is Aem = G * lambda^2 / (4 * pi), where

lambda = the wavelength
G = the antenna's numerical power gain in the direction being analyzed

The gain in dBi = 10 * log[base10](G). For convenience, use meters for length dimensions, so the aperture is in square meters and the wavelength is in meters.

This means that if we have a field with power density Pdi striking an antenna with power gain G1 (in the direction the field is coming from), the antenna can deliver Pdi * Aem watts to a conjugately matched load.

Now let's connect this antenna to a second antenna with numerical power gain G2, and assume that the two are perfectly matched to each other. That is, the input impedance of the second antenna is the complex conjugate of the impedance the first antenna has when driven. Also assume no loss in the connecting line.

The power delivered to the second antenna is then Pdi * Aem watts.

The second antenna will radiate a field with power density equal to G2 times that of an isotropic antenna supplied with the same power, or

G2 * (Pdi * Aem) / (4 * pi * r^2)

where r is the distance from the antenna in the direction in which the gain is measured.

Combining these to find the ratio of power density of the field radiated from the second antenna to the power density of the field striking the first antenna, we get:

P density ratio = G1 * G2 * (lambda / (4 * pi * r))^2

This is the numerical gain you'll see between the field at the location of the first passive receiver antenna to the field at a distance r from the second (radiating) passive receiver antenna. A ratio of less than one represents attenuation rather than gain. The gain in dB is 10 * the

base 10 logarithm of this ratio, with negative results representing attenuation. That is,

Overall gain (dB) = 10 * log[base 10](P density ratio)

Now let's look at a couple of examples. For simplicity, assume that none of the original field arrives at the detector location; that is, there's a perfect shield or obstruction between the original field and the detector (technically, the detector's antenna). It doesn't matter what kind of antenna is physically connected to the detector for this analysis. In real life, the detector would probably be a receiver, but I'll call it a detector so hopefully its antenna won't be confused for either of the two passive receiver's antennas.

Let G1 = G2 = 10 -- both antennas comprising the passive repeater have 10 dBi gain (although don't forget that G1 and G2 are numerical, not dB gains -- the two numbers just happen to be the same in the case of 10). Wavelength = 30 meters (10 MHz frequency), and r = 10 meters -- we've put the detector's antenna 10 meters from the second (radiating) passive repeater antenna(*).

Working through the numbers, the power density at the detector's antenna is 5.7 times, or 7.56 dB greater than, the power density striking the first antenna. So the signal is stronger than it would have been if we'd put the detector's antenna right where the first passive repeater antenna is. Don't forget, though, that it took two 10 dBi antennas to get that 7.56 dB gain.

But now let's look at the same setup but at 150 MHz (2 meter wavelength). The power density at the detector's antenna in this case is just 2.5% of (or 15.96 dB less than) the power density of the field striking the first antenna.

In all cases, if we move the detector's antenna twice as close to the second (radiating) passive repeater antenna, that is, to 5 meters away, we'll gain 6 dB; if we double the distance to 20 meters we lose 6 dB. Before you say, "Aha! let's put the detector antenna 0.000001 meter from the passive repeater antenna and get incredible gain!" you have to realize that the antenna gain is achieved only in the far field, so you've got to keep a good part of a wavelength away for the rules to hold. Actually, 5 meters is almost certainly too close for the gain to be valid at 10 MHz. The actual gain at any distance and field strength for a given input power could easily be determined for a particular antenna by modeling.

Why does the wavelength make such a big difference? Well, think of the size of the field each antenna intercepts. Both the 10 MHz and 150 MHz antennas have the same gain, so the former is dimensionally 15 times larger than the latter, or 15^2 = 225 times the area. Consquently, the 10 MHz antenna intercepts 225 times the power that the 150 MHz antenna does(**). 225 is exactly the ratio between the 10 and 150 MHz results of 5.7 and 0.025 (if carried out a few more places).

If you know how much signal strength margin you have at the point where you put the first passive receiver antenna, you can use the equation above to calculate how much antenna gain you'll need for your passive repeaters and how close you'll have to put your receiver's antenna to the second (radiating) passive receiver antenna, or how to trade the two. Note that I've assumed perfect match and no loss. If, for example, there's loss in the transmission line between the two passive repeater antennas, that loss in dB will directly subtract from the overall passive repeater gain (or add to the overall passive repeater attenuation).

(*) 10 meters is only 1/3 wavelengh so a bit close. The nominal antenna gain might not actually be realized at that short distance. But I'll assume it is.

(**) Please don't infer from this that aperture has any obvious relationship to physical antenna area except in so-called "aperture antennas" such as horns or parabolic antennas which have large physical dimensions. The antennas under discussion have apertures proportional to their physical areas only because they're assumed to be physically identical except for a scaling factor. In general, antennas with widely different physical areas can have the same aperture, and antennas with the same physical area can have widely different apertures.

Be careful when modeling antennas with offset feed. It's very difficult to prevent common mode current flow on the feedline of offset feed antennas. You might be able to keep the common mode current down to a reasonable level with a couple of good current baluns spaced about a quarter wavelength apart, but otherwise the feedline will be an important part of the antenna and needs to be included in the model. You'll have to include the whole conductive path to the Earth in order to get good accuracy, and this path might not be easy or possible to determine.

My 1999 Toyota radio has just started acting strangly: the FM seems fine, but the AM radio is producing a wierd kind of static every time I drive over a bump. Even a little bump. The "static" sound is similar to the sound you hear when listening to AM during a storm and there is lightening nearby. It's quite annoying.

Is my radio going bad?
Is the antenna connection loose?
Could it have to do with static control (somehow) because of the winter weather?

Any advice?
Thanks!

Jim,

Have you thought about going vertical? I'm lucky enough to have room for a 160m dipole, but also have created a shunt-fed 160m vertical from my existing tower. The vertical is barely adequate for "local" QSOs but outperforms the dipole beyond several hundred miles.

I also notice that Cushcraft has just released a commercial 160m shortened vertical (30-36 feet). I have not seen any reviews of this antenna yet -- and would generally prefer to build-it-myself -- but there may be some characteristics of the antenna that you could employ.

Sounds like a loose wire or something scraping metal on or near one section of the whole radio/antenna setup. if you grab a piece of wire and scratch it back and forth on the radio case (metal) you will get the same effect. Start looking for loose connections/case/wires under dash etc.

Any time 2 pieces of metal rub together they can create the radio
static you describe. Something's loose in your car and it's not
necessarily the wiring.

That depends on its r-f ground. Horizontal plane radiation from a 1/4-wave vertical could be worse than the horizontal 1/2-wave dipole if all of the induced ground currents around the vertical aren't collected and returned to the tx/antenna system.

And verticals of some heights have zero radiation in the horizontal plane -- one wavelength, for example.

1235. Noisy Antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-07 15:02:20 UTC
From: glenn.b.dixon@gmail.com
Message-ID: <1139323498.740521.243970@o13g2000cwo.googlegroups.com>
Source record: 64595

I just put up an offset fed dipole cut for 80 meters, up 40 feet, though the ends bend down a bit. It is fed with 40 feet of 177 ohm open wire twin lead, and a portion of the antenna goes over the top of my three-story house. At the feed end of the twin lead is a Guanella two-core 4:1 balun to sixty feet of RG-8U (actually, the better stuff--RG-216?) to the shack. The coax has a common-mode choke just before the tuner. The antenna tunes well on all bands 80 and above. The balun was tested to have less than 0.1 dB loss over HF and impedances from 25 to 100 ohms on the 50 ohm side.

Last night was the Spartan Sprint, a QRP CW contest that provided many weak signals suitable for evaluating the antenna. I tuned the contest in on 40 meters, and found a few stations calling, but S/N on all signals was never high enough to copy solid.

I then went to the ham radio room at our city building a block away, and listened to their late-model Kenwood on a G5RV up 30 feet. On the same frequency with an SSB bandwidth I received at least a dozen signals, solid copy on each.

I took the Kenwood (I have permission to do this) to my shack and hooked it up to my new antenna (without the tuner--the Kenwood has a matcher inside) with results somewhat between what the city antenna gave and what my own radio gave.

Now here's the rub: I'm willing to accept the idea that my antenna is noisier and needs work, but an experiment I did puzzles me: when I evaluated the Kenwood with my antenna I left the matcher on the settings it had for the G5RV antenna. As mentioned, I could hear stations better than with my radio, but not as well as the g5rv at the city building. The noise level (as measured on the Kenwood) was about s2 on the g5rv, and s5 at home. About five signals were copyable in the SSB bandwidth I had selected.

I then tuned the Kenwood to the dipole. It tuned successfully, and when I was done, the noise had gone to s9. This is not a surprise since the matcher has an effect on signal and noise strength. The surprise was that all signals instantly dropped below the noise, with only one signal that could even be heard. The radio's performance at this point matched my original evaluation with my ICOM and an external tuner matched to the antenna.

The engineer in me says that though tuner settings can affect how well signals and noise couple to the receiver, they should not affect overall S/N as long as we are within the dynamic range of the radio, but I definitely saw an effect. I finished the experiment by returning

to the city building and verifying the band was still active.

I think I know what might be happening and am designing an experiment to verify this, but would appreciate any speculation antenna experts may have. I doubt it is something like signal overload--rather, I think the antenna was really the culprit. Has anyone else seen this effect?

Thank you,
Glenn Dixon AC7ZN

To get a relative indication of unbalance on the feeder, run it thru
a toroidal core with a few turns of wire wound around for a secondary
winding. Recitify the secondary voltage, and read with a DC
voltmeter/microamp meter. If you don't have a toroid big enough to fit
around the feeder (likely if you are using >300 ohm line), it should be
ok to transition to smaller line for an inch or so to go through the
toroid.
You are wanting to read the balance of the antenna. The antenna by
itself can be completely balanced, but when you add the transmission
line, the antenna system can become quite unbalanced. The above
detector will give you a relative indication of feeder unbalance, which
I guess you really want to read.

Thanks for the tutorial. The only time I was (remotely) involved in a
similar set up was in some very early cell phone demos inside buildings
where the cell site was not very close. Two antennas were used, but two
sets of filters and amplifiers were used to get considerable power gain in
both directions. in/out of the demo room.

MFJ makes a $99 RF current meter (MFJ-854) which does this and provides
30 ma to 3 amp FS readings. They claim 1 ma is detectable. One
milliampere of unbalance is not worth talking about.

Gary's do-it-yourself suggestion is a good one. Easy to build and
interesting to calibrate. Of course, if the interest is only in
determining which of two alternatives creates the greater unbalance, the
DIY approach is hard to beat.

Both methods will probably require reducing line separation. The MFJ
accomodates only 1/2 inch in the clamp. Both methods also leave you with
an instrument useful in tracking down RFI problems.

Source record: 64604

Hi Bryan

It appears as though we have woken some major discussion... Someone may even do the calculation for you!

The parabolic dish/grid "focuses" whatever power you start with. This means more power or a higher gain antenna will mean more signal at the far end. The result is additive. The power limitation is a legal one. I dont remember whether it is 1W (30dBm) or 4W (36dBm) EIRP for 802.11/2.4GHz. The term EIRP refers to the power of the focused beam as if it was the same level that would be obtained from a theoretical point source antenna. In simple terms if you take the 4W EIRP and subtract the antenna gain you will get the output maximum allowed at the transmitter. In your case this would be;

36dBm(EIRP) - 24dB(antgain) = 12dBm or about 8mW

Keep in mind that you also have to allow for cable loss between the transmitter and antenna. Numbers in the order of 6-12dB are not uncommon so you would have to subtract this as a system loss. A 6dB loss would bring your max transmitter power up to 18dBm or 32mW. Keep in mind that advertising can be confusing. A bigger number on an antenna brochure always seems better than a smaller one, but may be misleading. I dont quite understand you statement about the grid antenna being adjustable in power. (Also note cable loss affects the receiver too so you should try to minimise it)

These are pretty low levels and are unlikely to upset any passing birds! I wouldnt however sit in front of the dish for any extended length of time. I'm just paranoid though!

re joining the antennas, yes just join the pigtails exactly as you mentioned. Note others comments on the greater effectiveness of a billboard reflector though. I didnt mention this thinking you wanted to keep the visual effect small. I guess you could always disguise it as something else though!

The higher the gain of the passive devices the larger the signal that will be relayed. Higher gain means narrower or sharper directivity. The problem is to work out how much you actually need without just trying it and maybe failing. You could equally as well go for a couple of your 24dB grid antennas joined.

I should also mention that one of other major importances of a directive antenna is to reduce multipathing or the signal bouncing off objects to the side of the main path and getting to the antenna a little later than the main signal. This can cause problems and slow your link down, may

even make it unusable.

Oh and speaking of which did you try bouncing the signal off the house?

I dont see the antenna mounting (separation) on both sides of the
utility pole as being a problem.

Also checking. There is a max distance parameter that will need tweaking
in a 802.11 setup. Make sure that is set to 2km or so.

Cheers Bob

//sympathy flag set//

Discussion of technical subjects between some hams can be frustrating to
listen to when you are accustomed to a lifetime of technical discussions and
experience with a sound understanding of the basics in the field. It is
indeed baffling to them, with all the seemingly black magic rules,
semi-truths and misconceptions they have heard over the years. Couple this
with one or two personal experiences which provide anecdotal "evidence" and
you can here some truly interesting interpretations. Some of it is amusing;
some is sad and some degrades to childish. A genuine interest is a jewel and
when someone expresses this, it is a joy to pass along the knowledge you
have gained over the years.

Roy,

While somewhat experienced in the field, I always enjoy your
knowledgeable and clear explanations. Some are informative, some are what I
already understand and some serve to affirm what I believe to be true based
on some related, but not direct experience. The latter is a joy as it
affirms that your (my) basics haven't failed you (me).

Thanks, Keep a stiff upper, and all that.

//sympathy flag cleared// (:-)

Many times when rotors are changed or removed for machining the static spring is left out. Static electricity is built up on the tires and with no path to the body builds up until a bump is hit causing the wheel to bounce up, reducing the gap to the point discharge takes place.

No takers, but it's only been a day... Antenna on a metal tube... sounds difficult. Body roll confounds the problem. Sounds like your experiments worked. What were the probs? Antenna drag and resulting instabilities?
I can only suggest searching on "patch antenna". Then there is a slot antenna, but fabricating this as part of the body without weakening the tube sounds equally difficult...and the dimensions may be all wrong to fit the antenna correctly.

If I shift into speculation mode, I'd think about an end-fed antenna which trails, but your "metal" rocket sounds as though the exhaust will be rather hostile compared to an Estes engine.

Reminds me of an idea I have always wanted to try on the small model rockets. Namely:
A on-board transponder for distance measurement. A 10 Meter one transistor FM receiver feeding a simple 2 meter 1-2 transistor FM, xtal controlled transmitter.
High power (100w if needed) 10 M mobile transmits a tone to rocket. Therefore airborne RX and 10M antenna need not be anything great. Rocket transponds tone on 2M FM. 2M antenna do-able on small rocket. Mobile receives tone. Black box (easy hardware) in mobile simply counts a reference freq from time of transmitted tone rising edge to received edge. Suitable accounting of internal delays and choice of reference frequency gives simple, direct readout in feet or whatever units desired. Calibrating the display horizontally on the ground is possible.

73, And good luck, Steve, K9DCI

Hi Roy,

MFJ makes a nice 81 dB step attenuator for a very reasonable price (about $70.00 as I recall) for those who don't want to build. In either case (build or buy), one still has to know how to make good use of it, which to my experience is more demanding than either pocket book or soldering solutions.

There are a LOT of neat things one can do with a 2 position switch and a step attenuator. For one thing, a lot of myths can be summarily dismissed (after getting enough data points...another problem that gets lost in the shuffle). One simple measurement on anything sky-wave based is completely meaningless. Things like path-length, time of day, etc. need to be "washed out" or "isolated" in order to come to anything even resembling a meaningful conclusion, and one is likely to arrive and multipe conclusions based on the array of variables one investigates. A step attenuator is an absolute essential for anyone who plays with gain antennas or wants to compare antennas. If expense is an issue, you have provided a great solution, otherwise, the MFJ works rather well for not a lot of money.

73,

...hasan, N0AN

1248. Antenna analyzer- no MW?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-07 19:40:57 UTC
From: chris <cpwendling@yahoo.com>
Message-ID: <1139341257.659885.24440@z14g2000cwz.googlegroups.com>
Source record: 64608

I've been thinking about springing for an MFJ (or other) antenna
analyzer
to check on the myriad antenna's I've got around the place.
I noticed that most of the analyzers on the market (like the MFJ-269,
for ~$350.00)
only go down to 1.8 MHz. I do a lot of work with xtal radio's
(DX'ing), and have a lot of different AM (MW) antenna's strewn about
the property. I was wondering why they cut that portion out of their
instrument? No demand? Too exotic?
Does anyone know if the analyzer could be modified (add some
inductance, etc. somewhere) to bring it down to about 500kc? Thanks!
Chris, AI4MI

This is the best method. Be sure to run both conductors through the core.

The core itself will act as something of a common mode choke (current balun) unless you terminate the winding in a fairly low resistance. Terminating it will reduce its effect on the line you're measuring. I typically use about 10 turns for the secondary with 51 ohms across it. That gives an insertion impedance of 51 / 100 = 0.51 ohm, which is negligible. I prefer to do this so my measuring device doesn't disturb what I'm measuring -- if I want a balun I do it separately. I suggest using a second core/winding on just one of the wires so you can compare the total wire current to the imbalance current. It's very important to terminate the one on the single wire, and if you want to use the two for comparison, you'll then also have to terminate the other. A high-permeability "low frequency" ferrite core is best for these, like Fair-Rite type 70 series (72, 73, 77, etc.). Type 43, a very common type used largely for EMI reduction, is also ok.

If you terminate the winding in about 50 ohms, you can put your sensor at a remote location and run 50 ohm coax between the core and detector/termination without disturbing the reading except for the coax loss.

I don't recommend two RF ammeters as some others have suggested. They only tell you amplitude and not phase. You can have some pretty seriously imbalanced currents and still see equal meter readings.

Another option would be to make two identical transformers, one for each wire, and connect both secondaries to the same terminating resistor. Reversing one of the secondaries gives true vector addition or subtraction of the two currents, and then you can detect and measure the resultant in the normal way.

Out-of-phase connection of the two secondaries indicates the differential line current, or the in-phase connection gives the common-mode current (hopefully much smaller).

I think that should work...

Another thing to think about: most of the analyzers around are pretty much useless on low freqs anyway due to interference from AM broadcast signals.

I recently finished shunt feeding my tower for 160m, and found that my AEA CIA analyzer was completely useless trying to measure the feed impedance. In the end I just used a regular swr meter to adjust the shunt feed. I don't remember exactly how low the AEA goes, but it is below 1.8 MHz.

Excellent idea. But be sure to use a fairly low value of terminating resistor for this and any time you run just one of the conductors through the core. Otherwise you'll be putting a significant impedance in series with your feedline conductor, causing mismatch and/or loss. The insertion impedance, that is, the effective series impedance of the core, will be Rt / N^2, where Rt is the terminating resistor connected across the secondary winding and N is the number of secondary turns. Lower values of terminating resistor will reduce the detector's sensitivity, but this won't be a problem at moderate or even quite low power levels.

Yes, it's ironic that the one thing "antenna analyzers" are pretty useless for, in an urban environment at least, is analyzing antennas.

Some time back I mentioned how a "half wave filter" could be used to reduce out-of-band signals without disturbing the measurement too much. The postings should be possible to locate at groups.google.com. Please read all postings, because I recall incorrectly saying that the filter could be used at frequencies lower (for a lowpass) or higher (for a highpass) frequency than the design frequency. I later corrected that. A given filter is good over only about one HF band without significant disturbance of the measurement.

Don't panic!

There is an Italian analyzer, 0-60MHz for about 150€ (180 US $) which is based on the AD9851 from analog devices.

You need a computer so it's not a handheld.

It's a "half VNA", giving +/- 90 degrees phase info but that is normally not a problem as it's easy to find out the sign anyway.

A new version is coming soon and covers 0.1 Hz to 160 MHz. I think I saw a price of 240€ on that one.

The TenTec TAPR VNA, 0-100 MHz is a "real" VNA with full quadrature 360 degree phase info.

However, you do still need a computer.

Cheers

Dan / M0DFI

I think one problem is that your feeding it with open wire line. An off set feed dipole is in no way a balanced load. This means the feedline is an active part of the antenna and is picking up noise. Feed that way it's what I guess they call a Carolina Windom where the feedline is used to give a bit of vertical polarization to the antenna. In a G5RV the open wire line is supposed to be a matching section on 20m and a bit of feedline on the other bands and as its center feed the feedline is not supposed to be a active part of the antenna.

Chris,

The problem with low cost analyzers is that they use broadband detector diodes. Strong local AM radio stations will cause an output from these diodes and generate erroneus results. In fact, MFJ suggests a highpass filter before the instrument in order to alleviate this problem (in areas with strong local AM stations). MFJ discusses this issue in the MFJ-259B manual which is a free download @ http://www.mfjenterprises.com/manuals.php.

However, a German ham has modified his unit for operation from 40 kHz to 1.8 mHz. This is not a trivial mod and it is described on page 88 of his manual @ http://www.darc.de/distrikte/f/27/MFJ259B_SWR584B_Handbuch1v4.pdf

Unfortunately it is all in German so you will have to use Google to translate the appropriate sections. BTW - this is the most comprehensive user manual for this analyzer available anywhere. Includes testing, calibration, schematic diagram, numerous mods, operating tips and techniques, and how to build accessories.

Hope this helps - Roger

1264. 4nec2 on Windows-XP ?

Hello...,

I would very much like to hear about users who did or did not succeed running the latest 4nec2 version (5.6.0) on windows-XP.

This because some now and then I get 'strange' problem-reports for problems which I am not able to reproduce on the XP systems I have overhere. I would very much like to tackle this problem, so any information about this is very welcome.

Thanks in advance,
Arie.

O.K. then.....I'm doing it! I figure that tommorrow I will add
65ft MORE to each end. Currently,the "sides" are 70ft. per side.
the thing "OF ISSUE" here IS that this antenna is a "linear-loaded"
dipole of 140ft. total,across the top. Each section IS 210ft of
wire in a "folded" condition. I need to get to that 260ft or so feet
long across the top. I'll let you guys know how this works out.
I bet thaat adding this wire will affect the ladderline length.
Paladin ps-I want this antenna to be BEST on 160m phone

So far, correct. But, that 10,000 J equates to 1E16
[100,000,000,000,000,000] watts peak power.

There is a thermal shock wave that occurs in the wire. There is a
transient magnetic wave in the wire.

The failure mechanism has been empirically correlated to peak power
times [pulse width^1/2].

The wire, or portions of it goes away!!

1271. Another Car Radio static question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-09 14:17:26 UTC
From: Jeff Dieterle <jdieter@nospam.carlnet.org>
Message-ID: <10cd5$43eb4ef3$424980b2$32629@COMTECK.COM>
Source record: 64532

I drive the same route everyday. On the same 1.5 mile section I get a very loud buzz and on top of the buzz a higher pitched periodic hum lasting for 10 seconds and occurring every 30 seconds overpowering everything on the low end of the am band. There is a 3-phase distribution line along the road, would a failing insulator create this type of problem, I thought that would be more localized than covering a 1.5 mile stretch. Along this 1.5 miles I travel 3 different directions and the intensity doesn't change much and it doesn't make any difference what time of night or day. Near one end of this area, there is a transmission tower of some type. The tower has been there long before cell phone towers started sprouting like weeds, also it doesn't have the dish array near the top just a straight tower, probably 15' sq. at the base and 75' tall.

Is the person or company responsible for creating this type of interference obligated to correct the cause?

Dale, W4OP wrote:
"A folded dipole is the same length as a classic wire dipole. The folded term relates to two parallel conductors not the overall length."

true. A 1/2-wave folded dipole has the same radiation pattern as a straight dipole. Its feedpoint resistance is higher, depending on the number of conductors in the dipole and their relative sizes. Another difference is more significant. The folded dipole is also resonant when it has two wires and it is only 1/4-wave long. It is resonant because its circumference is then 1/2 wavelength.

The feedpoint resistance of the resonant 1/4-wave long center-fed folded dipole made from the same diameter wire all the way around is 6000 ohms. Special matching may be needed, However, gain is only 1/2-dB less than a 1/2-wave dipole and its radiation pattern is almost the same. Its bandwidth is only 5% of its center frequency while the bandwidth of the 1/2-wave folded dipole is 45% of its center frequency. Bandwidth of the thin single-wire center-fed dipole is 34%.

Arnold B. Bailey is the source of this information in "TV and Other Receiving Antennas".

Jeff Dieterle wrote:
"Is the person or company responsible for creating this type of interference obliged to correct the cause?"

Maybe. I doubt that leaky insulator noise generates the interference described. It would not likely last for only 10 seconds with a 30-second repetition rate.

Such an interference with different duration and repetition from Jeff`s used to plague my company at Houma, Louisiana. Our offshore division for the Gulf of Mexico was stationed at the Houma Airport. It turned out to be caused by the U.S. Government`s radar. Every time it swept our way, it broke the noise-squelch we used on our FM receivers, giving them a click and a buzz. We all wanted to fly safely so we never complained.

>Is the person or company responsible for creating this type of interference
>obligated to correct the cause?

It depends.

If they're radiating RF in excess of FCC part 15 limits, and do not
have a license to transmit in whatever frequency band they are using,
then they're very probably obligated to fix the problem or to shut
down whatever equipment is radiating.

If they're transmitting in a frequency band / allocation for which
they have a proper license, and if their transmission isn't leaking
spurious frequencies in excess of the FCC limits, then they're
probably quite legal. In this situation, what you'd hearing would be
considered to be "undesired reception" - that is, your car radio is
being overwhelmed by a strong signal outside of its normal passband -
and the FCC would consider this the fault of your radio.

Without doing some spectrum analysis and direction finding it's hard
to distinguish the two from the symptoms you report.

Hal Rosser wrote:
"(one acts like a receiver, and the other acts like a transmitter.)"

Back-to-back antennas both act like transmitters. Neither cares if its energy came from radiation sweeping it or fed to it from its feedline.

The most energy any antenna can extract from a passing wave is 50%. That is only when the receiving antenna is perfectly matched to its load. In this case the load is an identical antenna, so the chances for a match are good. But, at least 50% of the energy captured by the receiving antenna is going to be reradiated by that antenna right back in the direction it came from.

Another problem is the rapid decline with distance in the first wavelength from the antenna. It losses 22 dB in field strength in the first wavelength from the transmitting antenna. After traveling through a second wavelength from the antenna (distance doubled from the antenna) the field strength declines by another 6 dB. It loses 6 dB every time the distance doubles. So, after 4 wavelengths, total loss will be 34 dB.

At great distances form the transmitting antenna, double the distance is such a great distance that the field strength hardly varies at all even when traveling directly toward or away from the transmitter.

It is obvious that path loss is a function of frequency and distance if only from continuous expansion of the sphere of the electromagnetic wavefront. There are less watts per square meter when the watts are the same but the number of square meters is growing. Our initial loss distance was determined by wavelength which is inversely related to the frequency.

Best regards, Richard Harrison, KB5WZI

I've been using a "shorty" version of the G5RV (not the full length
version, due to space limitations -- mine is capable of operating on 40-
10 meters) with moderate success, even at QRP power levels. Rig is an
FT-817 with no amplifier, so max power is five watts, often quite a bit
lower.

This is a bit misleading. Typically, an antenna extracts only a tiny fraction of the energy from a passing wave. The actual amount of energy it does extract is expressed as its "capture area" or "effective aperture". A recent posting I made includes a way to calculate this if you know the antenna's gain. Because the "capture area" is usually a tiny fraction of the wave's total area, only a tiny fraction of the wave's energy is extracted.

There's more nonsense, old wives tales and gobbledegook generated by
THAT antenna than all other antennas put together.

Just erect the longest and highest dipole you have space for and feed
it with 450-ohm open-wire line all the way to the shack. If you don't
have a balanced tuner, use an unbalanced tuner with a choke balun. An
unbalanced tuner will probably be better anyway.

To lengthen a dipole make an inverted-U. Or make a Z with it.

Reg.

Richard, that doesn't make sense to me. Such an antenna could be fed
with 1/4WL of 600 ohm open-wire line and achieve an impedance of 60
ohms looking into the matching section. That's just too good to be true.

I just ran an 80m folded dipole on 160m using EZNEC. It says the
feedpoint impedance is 32+j1900 ohms. That's a long way from
resonance and 6000 ohms.

Chris,

I can't see the drawing but Wilson made several models of self supporting
tubular masts. These are now sold by US Tower as the MA-40, 55, and 70.
They have a rotating base option.

When my car radio had that problem, I FINALLY fixed it by running an extra wire from the negative side of the battery to the car's body. It was hard to trace an intermittent ground. I gave the ole multimeter a good workout that day.

> ...
> cannot seem to find any reference to "4nec4" on the website.

Yes that's correct. 4nec2 (for nec too...) does 'understand' both nec2 and nec4 in- and output-files.To switch from Nec2 to Nec4 use 'Settings->Nec engine->Nec4*.exe'.
However the interface between 4nec2 and Nec4*.exe is a bit more primitive compared to the Nec2 interface. This because of the unability of input-file redirection for the average Windows-based Nec4 compilations.

> I tend to have a bias towards GNEC

Ah, no problem at all. Choose what you like best !

Thanks for the feedback,

Arie.,

The trap is a coil and a capacitor in parrallel.
The antenna is for 40 and 80 meters and the trap works in the 40 mtr band.
From the feedingpoint to the trap is 2 times 10 mtrs (for 40 mtr) and then
some 7 mtrs for 80mtrs.
When you work on 40 , the antenna works only from the feedingpoint to the
trap because the circuit "cut" the antenna so you work then with 2 times 10
mtrs.
The manual says that traps can be measured,i tried by manual but no luck.

that raises a good question. had there been any engine work where they may
have inadvertantly left the ground strap from the body to the engine off or
loose? keep in mind as posted below the body is grounded to the engine
block, and the battery neg goes to the engine block.

An example of what Richard is saying is found when listening to a none-too-strong FM broadcast station: if a big airplane flies into the path near either end of the path, one will notice significant vector addition of signals (heard as flutter).

Billboard (reflector) type passive reflectors have several applications. One is to place the reflector on a high edge of a ridge that is not accessible part of the year (or that does not have electric power) so as to facilitate propagation along a valley.

"Passive Repeater" is used in about three ways: (1) large reflector; (2) back to back connected, gain antennas; and (3) back to back connected antennas with filter and gain blocks in the connection (sometimes, bi-directional).

This is not one of the Wilson MA series. I have the CT-70 that I
bought about 1979. The top section failed in a twisting mode back in
the mid 80's. I have kept up with maintenance and it is currently
installed on a free standing fixture with an electric boat winch to
raise & lower it. It spends most of the time at about 30 feet where it
is very robust even with a Cushcraft A3S installed.

On the list of things to do is the matter of a power tilt winch. I am
not as robust as I once was!

BTW, it was about $450 when I bought it.

Source record: 64558

Cecil, W5DXP wrote:
"Such an antenna could be fed with 1/4 WL of 600 ohm open wire line and achieve an impedance of 60 ohms looking into the matching section."

Exactly.

The actual impedance of the 1/4-wave folded dipole is an inverse function of the wire diameter. It can be chosen to present 6000 ohms. Arnold B. Bailey has studied the behavior, developed the formulas, and published graphs for the user to choose wire sizes for folded dipoles of either 1/4-wave or 1/2-wave overall length. He does a sample calculation and showes his work for one particular 1/4-wave folded dipole.

On page 414 of "TV and Other Receiving Antennas" Bailey writes:
"At first resonance (where the total wire length is 1/2-wave and overall length is 1/4-wave), the current in the continuous rod (entire wire length) approaches a constant value, varying from a maximum in the center (farthest from the drivepoint) to about 0.7 of maximum at the ends. For this reason the radiation resistance RR approaches the value for a constant-current rod. The practical value is approximately RR=570(l squared), where l is the nominal over-all length and equals 0,25 wavelength, thus resulting in a value of 35.6 ohms."

The 1/4-wave folded dipole shares some of the characteristics of a short-circuited stub. It is a resonant circuit element which converts the low impedance at its short-circuit into a high impedance at its feedpoint.

If the 1/4-wave folded dipole is a little short of 1/2-wave around its perimeter, it presents an inductive reactance. If a little longer electrically than 1/2-wave around, it presents a capacitive reactance.

Best regards, Richard Harrison, KB5WZI

Another product that works very well is Lawson 59933 Copper Anti-Seize Anti-Corrosion Compound
http://webapp.lawsonproducts.com/website/showItem?itemNum=59933
This is the same product that comes with a Butternut vertical antenna. It consists of a synthetic grease base, copper, thickener, and rust inhibitor. It can withstand temperature ranges from -65&#65533;F to 1800&#65533;F, which should be adequate for most ham applications.

Well, 40 channels should just be fine!

15 watts SSB should just be fine!

If you want more, get a ham license and be legal. It is illegal to
operate outside the 40 channels and have more that 15 watts.

The only legal method would be a good directional (beam) antenna on a high
tower.

Harold

Using EZNEC, I just did a frequency sweep on a #14 folded dipole
around half its design frequency. There were no apparent resonant
effects. How big does the wire have to be for a 130ft folded dipole
to exhibit a feedpoint impedance of 6000 + j0 ohms on 160m? Why is
no one using such an antenna on 160m?

1303. help appreciated with unusual j pole feed

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-10 20:33:48 UTC
From: kevin <khorseman@lineone.net>
Message-ID: <dsitdnopv1@news8.svr.pol.co.uk>
Source record: 64564

hi there, i'm looking for some help with a j pole antenna, it's actually a vhf marine antenna so i hope it will be ok to ask here.

my problem is that this antenna used be atop the mast of my yacht untill it blew off breaking the end fitting and pulling free of the coax, because these things are quite expensive and don't seem to last that long, I decided to try repair it as a spare.

It fits inside a fibreglass tube, so I carefully cut through the tube and pulled out the antenna parts, which are all intact.

my plan was to solder some coax to it and put it back in the tube, then glass the tube back together, but this is where i ran into trouble, i'm unsure where to afix the coax.

the antenna i believe is a j antenna, with a 3/4 wave leg and a somewhat less than a 1/4 wave leg returning from the base, however there is no connections on this stub part where the coax has been connected, i had expected there would be.

There is, however, 2 pins below the 2 upright legs, these are not electically connected to the upright stub elements, (the 2 upright elements are joined across the bottom). These 2 pins have a length of insulated wire attached to them which stretches over and parallel to the uprights of the stub. The 2 pins are staggered in height which means 1 side of this insulated wire run is approx 75 mm and the other side is approx 70 mm, it runs like an inverted v up the stub from these pins at the base.

I'm assuming that the coax should also be soldered to these 2 pins and interacts with the antenna through induction or something. If this is correct does it matter which side of the coax goes to which pin, neither of them are conneced to anything other than each other through the insulated wire, which as i've said, runs above what i beleive to be the antenna stub section.

or should the coax be connected at the top of the stub, (a halfwave from the top), i can't see any sign that the coax was previously fixed there, but then there is no sign that it was previously connected anywhere for that matter

hope this makes sense and someone is able advise, thanks for looking and if you can help thanks again.

if this all sounds like nonesense, i may be able to put a picture as an attachment but i'm unsure whether it is acceptable in this group.

kevin

Source record: 64565

You should realize that this antenna is much narrower banded than a half wave dipole. Using a transmission line matching section with such a high transformation would probably narrow it further.

The folded dipole described by Bailey (his data sheet 10-10) can be easily modeled with EZNEC or a similar program. A transmission line matching section can be included in the model if desired.

Hello:

Dumb question, I know, but just can't find a good pix and callout on the web. Some of the ones I did find don't even agree.

For a length of coax with a connector on each end:

The Male UHF is PL-259 let's say.

But on the other end, for a Female of the same connector type/series, is it called a:

PL-258 ?
or just a PL259 Female ?
or... ?

What's the correct designation for the Female ?

Know any good links showing the correct designation and a pix of ?

Thanks,
B.

Uhhh Robert, a female is a socket, not a plug. :-)
If I remember right, the mating socket is an SO-239.

IIRC, PL-259 was a part number specific to a (so called) UHF male
connector (plug) for RG8 size coax and with a particular braid anchor
scheme. More recently, the term seems to be used to describe any UHF
male connector for any sized cable.

S0-239 was the part number for a specific panel mounting UHF female
connector (socket) with a solder pin for centre conductor connection.
Again, the term seems commonly adapted to any female UHF connector.

Perhaps the better generic terms are UHF Male and UHF Female, but it
seems people like the more technical sounding PL-259 etc. When we talk
of BNC series connectors or N type connectors, we don't usually use a
specific part number as the designator for the whole series... but
that seems the common practice for UHF connectors.

most of the time you just put pl-259's on both ends since you are going to plug into a device that has an so-239 socket on it. if you need an extension cable you mate two pl-259's with a barrel connector, sometimes known as a pl-258.

Your gonna love this.

It's an SO-239.

Of course, there's the chassis mount, the cable attach, the
female-to-female feed-through, and more varieties.

Standards ARE GREAT!
And, there are sooooo many to choose from!

Anyway, it's "SO" for SOcket, and "PL" for PLug.
The PL-255 is the ol' venerable 1/4", mono audio plug.

1310. db Question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-10 23:46:13 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <CO2dnTNEFaEiuHDeRVn-oQ@comcast.com>
Source record: 64571

Hello:

When a table gives the attenuation (at some freq.) for a length of a
particular coax in db,
are they referring to db in voltage or db in power ?

Is is correct to ask a question as simply as the following:

If the attenuation is given as, e.g., 2 db, what Percentage therefore of a
received signal is "lost"
going thru the coax length ?

Thanks,
Bob

Decibels are a means of expressing a power ratio when used properly.
Of course, the power ratio is implied by a voltage or current ratio
when the impedance is the same in the two cases being compared. For
that reason, you can say that the power ratio in db is 10*log(P1/P2)
or 20*log(V1/V2) provided Z remains constant.

Nevertheless, voltage or current ratios are often compared using dB
where the Z is not the same, and stricly speaking, the power ratio
rquires an adjustment for the changed impedance.

If the loss is 2dB, the the ratio of power out to power in is
10^(-2/10) or 63%. If the impedance is the same, the ratio of the
voltages will be the square root of 63% or 79%.

Both. When voltage and power ratios are measured across the same single impedance, the ratio of voltages in dB is the same as the ratio of power in dB. That is, dB in voltage equals dB in power if only one impedance is involved. That's why there are different formulas for dB voltage and power ratios, to make this happen. And it's the case if a coax cable is terminated in its characteristic impedance so the input and output impedances are the same. It's under this condition that cable loss is specified, so the dB loss represents the loss of both voltage and current.

But when you compare the power at the output of a coax cable with the power at the input and the cable isn't terminated in its characteristic impedance, output and input impedances can be very different. The power loss will be somewhat higher than the specification (probably not much, when the matched loss is only 2 dB), but you can have much less or more voltage at the output than the input. So the power and voltage loss in dB can be very different, and you can actually have voltage gain -- although it can be argued that defining dB for a ratio of voltages across two different impedances is a bit shaky and perhaps not too meaningful.
>

100 * (1 - 10^(-dB/10)) ~ 37% is the fraction of power lost.

100 * (1 - 10^(-dB/20)) ~ 21% is the fraction of voltage lost.

These assume that the coax is terminated with its characteristic impedance.

And you don't need to put "lost" in quotation marks. It is truly lost as a signal, having been turned into heat.

How about "17-26B-TGN from RFDigital.com"? UHF cable-mount females are relatively rare, but can be found. Probably best to call them by a descriptive name, such as "UHF-series male connector for RG-213-size cable" for the plug -- or substitute "plug" for "male connector" -- and "female connector" or "socket" if that's what you want. If you really want to be specific, use a vendor's part numbers (as in the first line above), or numbers from some other standard you can mention along with the number.

But for casual conversation,
"A 30 meter length of RG-213 with a UHF plug on one end and a UHF socket on the other." If someone told me they had a cable with a UHF connector on each end, I'd assume they were both plugs.

There are three terms, idb, pdb, and vdb. They are not the same. idb and pdb have the same value: 10*log10 (i/i0), while vdb is 20*log10(v/v0).

Although the other answers given are correct as best as I can remember from school (long time ago), for most practical cb or ham radio purposes just remember that every 3db at a given impedance will 1/2 the power, from radio to antenna, or antenna to radio.

Not quite sure what all these are. But to express a voltage or current ratio in dB, you use:

dB = 20 * log(V2/V1)
dB = 20 * log(I2/I1)

and to express a power ratio in dB, you use:

dB = 10 * log(P2/P1)

If the voltages or currents are measured at the same impedance as the power, the numerical dB values will be the same. For example, let's suppose we have a 100 ohm resistor with one amp flowing through it. Then there's 100 volts across it, and it's dissipating 100 watts.

Double the current to 2 amps. The dB increase in current is

20 * log(2/1) = 6.02 dB

The voltage has also doubled to 200 volts, so the dB increase in voltage is

20 * log(200/100) = 6.02 dB

The power dissipation is now 400 watts, so the dB increase in power is

10 * log(400/100) = 6.02 dB

Cool, huh?

"A decibel is a decibel is a decibel". There is only one kind of decibel, and by definition it is based on a power ratio.

Decibels are always used for comparing power levels. If you're comparing current or voltage levels, you first have to convert them into a power ratio, and that is the reason why you have to use a different formula. Your starting-point was different, but the definition of the decibel remains the same.

There is a similar-looking term, sometimes written as either "dBV", "dBmV" or "dBuV", but that has a different meaning. Anything tagged on after the "dB" indicates a standard reference level. For example, "dBV" means "a power ratio in decibels, relative to the power level of a 1V rms signal measured at the same point in the circuit."

Ian,

Possibly. I assume that you are hinting at its performance from an impedance discontinuity point of view... however IMHO the greatest disadvantage of UHF connectors is also apparent at HF. UHF connectors depend on proper alignment of the vee points and notches and the coupling ring being very tight to provide ongoing reliable connection that doesn't degrade with vibration.

"UHF" is a bit of a misnomer I agree, but it has market acceptance in one of the largest market places, and that is the generic term for the things.

On another note, I was a little surprised to see the mobile phone manufacturers use the mini-UHF connector which inherited all the faults of the UHF connectors earth / coupling ring arrangement. Probably cheaper and a bit smaller than the TNC connector that they appeared to have standardised upon at the time. Then Nokia needed to invent a proprietary connector, all when SMA would have worked fine.

1325. Coax Losses ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-11 12:53:51 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <rd2dnRNI18_KQ3DeRVn-ug@comcast.com>
Source record: 64486

Hi,

Just getting started with all of this, and want to say a quick thanks to
everyone for all the help.

Another question:

Am I interpreting this more or less correctly:

Looking at all the different types of coax available.
Will be for a receive-only HF antenna.
Antenna will have to be in the backyard about 150 feet or so from house.

The db losses are beginning to add up; at the upper limit of my interest of
30 MHz
we are getting close to around 3.5 db or so.

Is it correct for me to say that the actual losses really aren't all that
significant or meaningful,
and that a good receiver, which I have, can easily make up for them ?

That the only thing of real concern would be the S/N ?

What are the caveats to my statement above ?

Thanks,
Bob

Source record: 64487

Bob,
You're right, for recieving the losses just aren't going to be that much,
and not
really something to worry a lot about. The average receiver ought to handle
and
make up for those losses. Losses will only be noticable on frequencies that
are
not fairly 'close' to one of the harmonics of the design frequency, and then
not
all that bad.

Source record: 64489

Hi Bob

Yes that is correct!

You may however get into larger losses from an "unmatched" antenna. This depends on how you feed it. If you (for example) ran a dipole type setup direct connected to the coax end, you will tend to have "notches" as the feedpoint hits a very high impedance value (eg the wire being multiples of a full wavelength but centre fed) Whether this will become an issue or not depends on how much loss occurs. If you (say) cut a dipole for 7MHz there will be this kind of problem at 14 and 28MHz. My gut feel is that both these freqs will be affected adversely. I havent gone to the trouble to guess how wide these "notches" will be but the problem will be worse the higher multiple you go. For transmitting purposes you get around this by using open wire feeder and a tuner. (And for the purists reading I have left out the topic of tuned feeders!)

As a general rule the impedance of a dipole dips to a minimum at resonance. A half wave around 75 ohms and 3/2 wavelengths 150 ohms (I think) In between there is a reactive component that adds to the overall figure. Without consulting some books I dont know the average nunbers off hand but impedances higher than a few thousand ohms are not uncommon.

Now for some quick maths.. If you try to feed an antenna with an input Z of maybe 2500 ohms with your coax - resulting in a 50:1 VSWR, you will lose about 3dB from the normal line length, plus another 10dB for the mismatch.. I's say that will be upsetting maybe from 21MHz up.

This is why its a good reason to use a broadband transformer balun at the antenna feedpoint. Realising that you are probably going to use something like that anyhow..

Apologies for the waffle.. You did ask though!

Cheers Bob

Coax cable, even old used stuff makes a great power cable. When I was
running hf mobile I ran and old piece of RG8 directly from the car battery
terminals to the rig. The dc current carrying capacity is more than enough
than for any rig. You also have the advantage of a completely shielded
power line and the battery acts as a giant capacitor, filtering out the fun
little rf components that are present in so many modern cars.
I only wish I had an old diesel rig, the kind without any electronics!

1331. how to build a high Q low loss counterpoise coil

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-11 16:16:41 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <dOSdnS3gZ5RxkHPenZ2dnUVZ_tCdnZ2d@comcast.com>
Source record: 64492

All,

Reg's counterpoise program predicts the effective ground of a centerloaded vertical on 75 meters can be improved by a tuned relatively short counterpoise system. This is dependent on a large, high Q, low loss tuning coil.

After some playing with the numbers a starting point for the design of such a coil is 200 mm diameter, 200 mm long, with 4 gage wire, and a pitch of about .7. This is obviously quite large.

My questions are:

1. Where is a good tutorial for large coils?

2. Are there coil forms for such coils?

3. What would the impact of a square or octagon be versus round?

4. How critical is spacing toward a high Q?

Thanks,

Dan - kb0qil

Actually what I was taught was the standard unit is the BEL, named in
honor of Alexander Graham Bell. This is a large value hence the DECIBEL
or 1/10 of a BEL is generally used.

Ian, GM3SEK wrote:
"Decibels are always used for comparing power levels."

True.

The decibel or dB is a power ratio. The dB alone says nothing about the quantity of power, only the ratio between powers. Thus, the dB is useful to express the gain of a linear amplifier or the loss of a resistance pad.

The dB can be used to express a power level by reference to some known quantity of power. In this case, the ratio is said to be so many dB above or below the reference level.

In the telephone industry, the most common reference level is one milliwatt. Signal loss is common. Cables fave loss per foot or mile. Attenuation is a division process. Amplification is a multiplication process. It is convenient to express the amount of power at a particular point in a system as being so many dB above or below a reference power of one milliwatt because adding and subtracting decibels gives the same answers as multiplying and dividing powers. Decibels above or below one milliwatt is usually abbreviated as + or - dBm.

DBa and dBrn indicate the interfering effect of noise in a communications channel. DBx is used to indicate crosstalk coupling into telephone circuits.

VU is a volume unit. Reference is to one milliwatt, same as the dBm, but the ballistics of the meter are specified so that a standard response is made to varying signal level.

Other dB units are easily contrived. There are dBw (dB referenced to one watt), dBk (dB referenced to one kilowatt), dBRAP (dB above reference acoustical power which is defined at 10 ro the minus 16 watts), etc, etc, etc.

Best regards, Richard Harrison, KB5WZI

Cecil,

They are elevated, based on Reg's program. It predicts that a relatively large, diameter about equal to length, 2 gage wire, high Q coil feeding a 2 meter radial about .5 meters elevated produces a resistance of just over 2 Ohms. This is at 3970 kc.

I have not tried this with another model, I seem to be unable to create coil descriptors to feed nec.

The fundamental construction questions relate to 'accuracy'. What would the effect be on Q be of a flat sides? What would the effect be if the wire (I plan to use 1/4 inch copper tube) had small 'ripples' in the wind.

Thanks - Dan

For a (fairly) comprehensive write up on the "decibel" go to
https://ewhdbks.mugu.navy.mil/decibel.htm .

Also:

Alexander Graham Bell
From Wikipedia, the free encyclopedia

Bell and decibel

The bell is a unit of measurement invented by Bell Labs and named after
Bell. The bell was too large for everyday use, so the decibel (dB),
equal to 0.1 B, became more commonly used. The dB is commonly used as a
unit for measuring sound intensity.

As I have heard it, this is a case of TLA (three-letter acronym)
collision. The full term for these connectors started out "Universal
High Frequency" (UHF) and did not imply that they were used, or good
for, "Ultra-High Frequency" operation.

You have the right idea. Signal/noise ratio is all that counts.

When receiving HF, feedline loss almost never matters. The reason is that atmospheric noise is strong, and unless a receiver is exceptionally noisy and/or an antenna is exceptionally lossy, the atmospheric noise will be much greater than the receiver noise.

The input to the receiver consists of the signal and atmospheric noise, to which the receiver adds its own noise. As long as the atmospheric noise is much greater than the receiver noise, you won't hear the receiver noise. Any attenuation in the antenna system will attenuate both the signal and the atmospheric noise equally, so the signal/noise ratio, which determines what you can hear, doesn't change. Any gain ahead of or within the receiver has the same effect.

Atmospheric noise declines as the frequency increases, so it might be possible to start hearing some receiver noise over it as you approach 30 MHz, particularly if your receiver is unusually noisy and/or the antenna system unusually lossy. As soon as receiver noise becomes audible over the atmospheric noise, the rules change. Then, attenuation ahead of the receiver will reduce the signal but not the receiver noise -- which is now the "noise" part of the signal/noise ratio --, so it *will* decrease the signal/noise ratio.

There's a very simple test to determine whether reducing the loss will improve your ability to hear signals. Tune your receiver to a spot with no signals in the frequency band of interest. Turn up the volume so you can clearly hear the background noise. Then disconnect your antenna(*). If the noise decreases, it means that atmospheric noise is dominating, so reducing loss won't help the signal/noise ratio. If the noise doesn't decrease, you're hearing receiver noise with the antenna connected and you'd benefit by reducing losses ahead of the receiver. You'll probably find that the noise will decrease by quite a few dB when you disconnect the antenna, and this represents the amount of loss you can add before your ability to hear signals suffers.

When receiving HF, about the only way you can improve your signal/noise ratio is by using a directional antenna. This will reduce the atmospheric noise coming from unneeded directions. Particular kinds of antennas can also improve the signal/noise ratio if the dominant noise is man made and coming from a nearby source.

(*) In a really marginal case, you might need to replace the antenna with a dummy load for this test -- an ordinary small 47 or 51 ohm resistor will suffice -- but it usually isn't necessary.

No, posting a picture here wouln't be acceptable. You could send it to those who ask, though. From your description, it sounds like the loop of insulated wire between the two pins couples to the stub--the 1/4-wave bottom of the antenna. I guess that stub is over 400mm long, so your wire only goes up a fraction of that distance. Someone may have engineered it, or they may have determined it empiracally, but it sounds to me like quite an acceptable way to couple to the antenna. And that seems like the most likely reason it's there, so that's where I'd connect the coax. I'd guess that there isn't much difference between the two possible polarities of connecting the coax to those pins.

Cheers,
Tom

Thanks for the info Mac. I see EZNEC/4 is $600.00, compared to $795.00 for GNEC. I have no trouble with the FORTRAN compiled program on my PC, although the graphics leave a little to be desired. Not sure what I will do to improve it yet. Not that interested in GUI inputs, as I find it far easier to edit NEC code directly.

It was an old Buick - no telling how much work had been done.
The ground strap was still there.
The 12¢ in of #12 from the negative terminal to a screw on the body fixed
it, and only cost 60¢ or so.
I had started tracing circuits from the + side, so it took longer to figure
it out than it took to find the ¢ key and the ¢ key on my keyboard.

I am putting up a T2FD (I think it's called a tilted terminated
folded dipole) In my attic. I have arthritis and am afraid to go out
on the roof anyway - so no diatrabs/platitudes about how much better I
would like a such and such antenna on the roof please. I think
antenna will probably be primary used over 9mc. I will probably SWL
only and don't intend to transmit on it. Can I use a regular 300ohm to
75ohm tv type of balun? I realize that for transmitting I would want
to keep the impedance high to keep core magnitizing flux low, but I am
reasoning that this is probably not an issue because receive microvolts
aren't going to energize the core with any flux anyway. In other
words I realize the impedance at 9mc is quite a bit less than channel
2. Am I hallucinating again?

1361. diff in coils between c_poise and vertload ??

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-12 20:03:34 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <2uCdnZM2ip4FCXLenZ2dnUVZ_s6dnZ2d@comcast.com>
Source record: 64522

I am using Reg's programs to calculate the Q and R of 'large'. These coils are in the range of 220 mm in diameter and long.

There seems to be a difference in the coil simulation between Vertload and c_poise. In particular c_poise seems more sensitive to coil wire diameter then vertload. Vertical load will create a coil with low R and a relativily small wire diameter and pitch, 2 mm and .2 pitch (it does not predict Q). C_poise requires a large wire diameter, 12 mm and a high pitch, >.8 to achieve similar R values.

Is there a reason for this? Am I missing something?

Is there a way to simulate Q and R for these coils with nec?? How would one create an nec representation for a coil?

Thanks - Dan - kb0qil

Hi Roy,

Thanks for reply re my older post on db question. Very clear explanations
by all.
Will put this as a new thread, though.

New at this, and relize I'm not thinking about this the correct way,
probably.

Relative to a receiving antenna's signal: what does the receiver actually
respond to; power or voltage at its input ?

Bob

Boy, that almost demands a philosophical answer.

But only almost.

Power. You can (and most really low noise receivers do) transform the impedance at the antenna into some ideal source impedance for the RF preamp (or mixer if you're operating in a band where atmospheric noise exceeds thermal noise by a good amount). Assuming an ideal* impedance transformation each time you can go from almost any source impedance, and the noise figure (which is a power ratio) will remain the same.

* Almost never a match. Low noise amplifiers usually do _not_ want a matched source for best noise figure, although there are ways to force it to happen.

Again, BOTH, tho, usually, sensitivity is expressed in Micro-Volts, but
the dB range also holds. And, to further confuse facts, sensitivity ,
at VHF/UHF/Microwave, uses Noise (figure/factor), which refers to a
Perfect Reciever (no internal noise), vs. your front end rf stage, or
at your antenna's output, before coax loss's and other things (like
BACKGROUND Received NOISE, ect.) Jim NN7K

The S-meter is actually a wattmeter. S9 = 50 pico-watts into a
50-ohms receiver input impedance.

It indicates signal strength and strength is watts.

A typical meter is scaled from -54 dB to +50 dB relative to S9.

That's why S9 is roughly half way along the scale - about 50 dB on
each side of it.

-54 dB corresponds roughly to receiver internal noise level.

+50 dB corresponds to receiver overload level.

> Relative to a receiving antenna's signal: what does the receiver actually
> respond to; power or voltage at its input ?

The short answer is power. You can't have one without the other, but you can choose to have various voltages for the same amount of power. A receiver has a fixed source impedance, and this determines the fixed relationship between power and voltage at its input. You can transform the impedance with various passive circuits, resulting in various other impedances with correspondingly different voltages. But this won't change the amount of power available from the antenna.

I'm avoiding discussion of the effects of impedance matching in order to keep the answer brief and hopefully clear.

1371. Smith chart/SWR/multiband dipole

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-13 02:34:21 UTC
From: Mark Sheffield <sheffield@earthlink.net>
Message-ID: <4urvu11tdnqqglu4j0o17alhvu4s6cp1bl@4ax.com>
Source record: 64432

I have a question regarding dipole length, SWR and Smith charts.

I'm using a 40/80 trap dipole and wish to lengthen the 80M portion to lower the SWR in the CW part of the band. I'm reading a SWR about 1.2:1 at 3.8MHz, 4.8:1 at 3.5MHz, which I wish to drop a little to ease up on the auto-tuner in my radio. I plan on adding a couple of feet and remeasure and I'll probably be close enough for rock and roll.

Now, I use this antenna on other bands - I can load it on 20 (SWR < 3), 15 (SWR < 3) and 10 (SWR < 3.2). I'd like to know what the impact of adding another 2 ft to each side will do on these bands.

So - looking at the Smith chart, I can draw my circles for each band and I can measure the physical length of each side of the dipole. How do I relate length to SWR on the chart? And, would this be useful to first-order? The whole function of a dipole is to radiate, so is this a very lossy system, or would this be close enough to lossless to get a good look?

Thanks for your thoughts

Mark/n0lf

It's impossible to say without knowing the L and C values making up the traps. You'll just have to try it.

> So - looking at the Smith chart, I can draw my circles for each band
> and I can measure the physical length of each side of the dipole. How
> do I relate length to SWR on the chart?

The relationship isn't a simple one. The SWR depends on the impedance, and the way in which the impedance changes with length and frequency is complex. Various approximations can be used, each with its own limitations on accuracy and range of validity. The only practical way to find the input impedance of all but the very simplest antennas is with a computer modeling program. Traps add another level of difficulty. If you know the impedance of the traps at a given frequency, you can model the antenna at that frequency. But to know the antenna impedance over a range of frequencies, you need to know what's in the trap, or you need to know the trap's impedance at each frequency. If you don't know what's in the trap, neither does the program.

> And, would this be useful to
> first-order? The whole function of a dipole is to radiate, so is this

> a good look?

I suggest trying a modeling program. The free EZNEC demo program from http://eznec.com is adequate for modeling simple antennas. Again, though, you'll need to know more about the traps to make even a guess at what the antenna impedance will be, whether you use a program or some approximate method.

Frank,

I am stuck with the GH descriptor. Do you have a tool that can generate a description of a coil 250x250 mm with 22 turns of 12 mm tubing?

Is it as simple as doing the division and filling in the entries?

Thanks - Dan

Try this Dan:

```
CM Inductor Q Calculation
CE
GH 1 500 10 200 100 100 100 100 2.5
GW 2 5 100 0 200 0 0 200 2.5
GW 3 10 0 0 200 0 0 0 2.5
GW 4 5 0 0 0 100 0 0 2.5
GS 0 0 0.001000
GE 0
EX 0 3 5 00 1 0
FR 0 9 0 0 3.7 0.025
LD 5 1 1 520 5.7001E7
RP 0 181 1 1000 -90 90 1.00000 1.00000
EN
```

I am sure you need to fine tune the structure, since I just guessed at the wire diameter at 5 mm for #4. Also not sure what you mean by "Pitch". This coils shows a Q of 2600 at 3.8 MHz. Don't know how 4Nec2 will handle it, but you could end up with 520 tags!

73,

Frank

From: Frank <ve6cb@nospam.telus.net>
Message-ID: <800lf.344$fQ1.22@clgrps12>
Source record: 64438

Hi Dan, Try the following code:

```
CM Inductor Q Calculation
CE
GH 1 500 11.36363636 250 125 125 125 125 5
GW 2 5 125 0 250 0 0 250 5
GW 3 10 0 0 250 0 0 0 5
GW 4 5 0 0 0 125 0 0 5
GS 0 0 0.001000
GE 0
EX 0 3 5 00 1 0
FR 0 3 0 0 3.7 0.1
LD 5 1 1 520 5.7001E7
RP 0 181 1 1000 -90 90 1.00000 1.00000
EN
```

Note that a detailed description of the "GH" fields are on page 20 of the "NEC - 2, Part III: User's Guide"; on page 20. The guide can be obtained at http://www.nec2.org/other/nec2prt3.pdf and is only just over 400 kB.

The coil dimensions you gave me are not physically realizable since 22 turns of 12 mm diameter wire will result in a coil length of 264 mm. I have therefore revised the wire radius to 5 mm. NEC will return an error if I attempt to input a radius of 6 mm.

NEC indicates the coil is 123 uH, and a Q of 4471 at 3.8 MHz. You would certainly have to silver plate the coil in order to maintain such a Q. The formation of copper oxide will cause Q degradation over time -- despite what some people seem to think.

I have thought of building hi-Q inductors with 1/4" copper pipe, but not sure how you can do the same with 1/2" pipe as it must be very difficult to bend.

Before building an antenna with such loaded radials I think it would be interesting to model it with non-loaded radials, and compare it with a "Lumped element" loading coil analysis.

Thank you. I will use this to figure out how to do this manually.

You are correct about the wire. Reg's program predicted 9mm not 12. I copied the wrong number. 22 turns of 9mm tubing is correct. I am not sure how physically realizable that number is.

Thanks Danny, Interesting paper. It certainly points out problems with silver plating. I must say I have never attempted to measure the Qs of inductors with and without plating, but it is something to think about. My point was more about the effects of copper oxide on inductor Q. It makes me think that the best way to prevent the build up of oxide is to use some kind of low-loss insulating material on the surface of the copper.

Source record: 64442

It is power which leaves the transmitter.

Power is what is received by the receiver.

So the S-meter is a power meter.

It is a great pity that the usual S-meter is scaled partly in S-units
and partly in decibels relative to S9.

But given that 1 S-unit = 6 dB, the modern meter scale fits very
nicely between receiver internal noise level and the receiver overload
point.

And, for example, it's so much easier to report signal strength as S5
rather than 0.047 micro-microwatts.

In the same vein, we could, of course, report a signal strength of 20
dB over S9 as S12 and be done with decibels.

Reg, G4FGQ.

The problem is that copper oxide isn't necessarily what forms on copper -- you can have copper chloride, sulfide, oxide, and perhaps other salts in various combinations and thicknesses depending on the environment. Likewise, silver will form all those salts.

If a chemical coating is a very poor conductor or a very good conductor, it won't appreciably degrade the Q. What will degrade the Q is a coating of sufficient thickness of an intermediate conductivity. I've tried for years to find data on the various salts of both metals, and found only very few.

But here's a quote from Chipman (_Theory and Problems of Transmission Lines_, 1968, p.81 - thanks to Wes, N7WS!):

"For many years it was thought that silver was necessarily the best plating material, since silver has the highest conductivity of all metals. However, careful measurements have shown that the corrosion products on a silver surface in ordinary atmospheres have intermediate conductivity, while those on a copper surface have very low conductivity. The result is that high frequency currents in a copper conductor flow almost entirely in the copper, below the surface corrosion layers, and the conductor's effective conductivity is that of the copper. For a silver conductor, on the other hand, an appreciable fraction of the current flows in the corrosion material of intermediate conductivity (the corrosion products are generally oxides and sulfides) and the effective conductivity of the conductor as a whole may be substantially less than that of silver. If a silver surface is protected against corrosion, including oxidation, by an extremely thin layer of plated or evaporated gold or by a low-loss dielectric coating, a silver plated conductor will have the lowest possible distributed resistance."

Chipman is obviously assuming a pure silver plating. As Danny's posted paper (http://k6mhe.com/n7ws/Plating.pdf) points out, "silver" platings are seldom pure silver, and are usually considerably less conductive than copper to begin with.

So it's been known for at least several decades that silver plating degrades Q over the long run, for a couple of reasons. But myths die hard.

Incidentally, I've found a couple of errors in the equations in the Fowler paper Danny posted (and which Wes N7WS kindly sent me years ago), apparently made during the copying of the original equations from their source. There seem to be some additional errors which I can't identify. If anyone knows where I might get a copy of the paper with the original equations, which is reference 10 (Astbury) in the Fowler paper, I'd be very appreciative. I've requested a copy of the paper through the local library, but it's likely to take a very long time to get. Perhaps some of the U.K. readers can make a suggestion, since the I.E.E. is the British equivalent of our I.E.E.E. I see from the I.E.E. web site that they're in the process of getting their older journals on line, but haven't finished the task. I don't mind at all paying a fee for it.

Bob,

To more directly answer your question...

One way to look at it is, that it is power which does the deed. To be fair, however, you can't have power without the voltage and visa-versa. This is when we are talking about receivers not OP amps. When a receiver receives a signal, there is a voltage present and current flowing at its input. They both occur. They both have to. Together these represent some amount of power. The receiver's input stage needs some RF energy to tickle its input so it can amplify it for the next stage. It is this power which is the energy. Because both of these quantities are there, we can use either to talk about the sensitivity of said receiver. Although not "normal" we could just as easily use current as a metric for receiver sensitivity.

Voltage is directly measurable so it is easy to use as a measure. It has been used over the centuries (not really) as a standard way of measuring what is happening in a circuit.

Power, on the other hand, cannot be directly measured it has to be calculated. Power, we know, is Volts times Amps or E x I. There are other ways to figure out power which I won't go into here, but this is how we must be satisfied doing it.

Why, you may ask then, do we use these power numbers instead of just voltage AND to make matters worse, why do we express them in some obscure thing like dBm? Good question! So we Engineers can keep you Hams in a steady state of confusion and therefore keep us in high esteem and power... Not really, but I'll stop here to see if this helped any.

If Roy's answer works for you, skip mine. I think an answer of mine on this must be in the archives.

Rule number one:
The Decibel is a measure of the ratio of two power levels ONLY, ALWAYS and NEVER anything else.
Rule Number two. We like to violate rules and drive newbies crazy.

However, I'll go back to Rule Number One first.

The so called "Voltage dB", "Current dB" and "Power dB' are all figments of your (well some people's)imagination. I used to have fun with new Engineers tripping them up on this. "Why are Voltage dBs twice as big as power dB's?". This is a false-reasoned question.

While, it is a fact that there is only one "kind" of dB, there are, however, three ways to _calculate_ them depending on what quantities you have at hand. Because Power is Volts times Amps, there is something special happening when we do the math. Lets call this V x A for this discussion.

For a simple case of doubling the power - or a power ratio of two to one:
In order to get twice the power, we need to change the Voltage AND Current enough so that VxA is twice what we started.
1 Volt and 1 Amp gives 1 Watt
For 2 Watts we'll need:
1.414 Volts and 1.414 Amps 1.414 x 1.414 = 2

Looking, we see that the voltage did NOT double. It went up less that twice.

However, we can calculate the decibel difference from the voltage difference OR the power difference. Using the "Power dB" formula for dB we get the correct 3.whatever dB and using the "Voltage dB" formula we get the VERY SAME amount of 3.whatever dB.

So the dB are not different, only the starting quantities and, therefore the formulas.

Rule Number 2:
We can, and, we do use the voltage formula (if it's there, use it... just like the mountain climber's answer to why does he climb the mountain...because it's there) in cases where we are not actually doing power ratio comparisons. Why? Because it is easy to compare large differences this way..that is, in the log format. Frequently, voltage gain in OP amp circuits is shown in dB even though there is practically an INFINITE power gain. This is because the input resistance is very high and the output resistance is very low and ignoring the resistance and ONLY

looking at the voltage gives erroneous dB numbers. HOWEVER, those in the field know and understand this and all is well in the universe, so to speak. By measuring the voltage gain, and using the dB formula, it is easier to show 50 dB "Voltage" gain than showing a gain of 100,000. Silly Engineers!

None. Different terms for the same thing. Perhaps time is the
difference...
In the early days, "Detector" was used. Why? Who knows! It worked. You
listen for a weak signal and if you were good, you could "detect" one.
Therefore that part of the receiver was the "Detector".

As we grew and became more sophisticated, we "modulated a signal on a
carrier". Since we used the same "detector" to capture it, we "detected"
the signal.
If getting on a plane is boarding and getting off is "de-planeing" then the
opposite of modulating must be "de-modulating".

It's like why is "Random Access Memory" called RAM when ROM "Read Only
Memory" is also "Random Access".

We're just a bunch of silly techno-geeks.

Technically, is it not energy that leaves the transmitter and is
received by the receiver?

Actual integration being performed by later receiver stages and/or the
human ear/brain?
